ABSTRACT

Context. The gamma-ray binary LS I +61°303 is a well-established source from centimeter radio up to very high energy (VHE; $E > 100$ GeV). The broadband emission shows a periodicity of ~ 26.5 days, coincident with the orbital period. A longer (super-orbital) period of 1667 ± 8 days was proposed from radio variability and confirmed using optical and high-energy (HE; $E > 100$ MeV) gamma-ray observations. In this paper, we report on a four-year campaign performed by MAGIC together with archival data concentrating on a search for a long-timescale signature in the VHE emission from LS I +61°303.

Aims. We focus on the search for super-orbital modulation of the VHE emission, similar to that observed at other energies, and on the search for correlations between TeV emission and an optical determination of the extension of the circumstellar disk.

Methods. A four-year campaign has been carried out using the MAGIC telescopes. The source was observed during the orbital phases when the periodic VHE outbursts have occurred ($\phi = 0.55\text{--}0.75$, one orbit = 26.496 days). Additionally, we included archival MAGIC observations and data published by the VERITAS collaboration in these studies. For the correlation studies, LS I +61°303 has also been observed during the orbital phases where sporadic VHE emission had been detected in the past ($\phi = 0.75\text{--}1.0$). These MAGIC observations were simultaneous with optical spectroscopy from the LIVERPOOL telescope.

Results. The TeV flux of the periodical outburst in orbital phases $\phi = 0.5\text{--}0.75$ was found to show yearly variability consistent with the long-term modulation of ~ 4.5 years found in the radio band. This modulation of the TeV flux can be well described by a sine function with a best-fit period of 1610 ± 58 days. The complete data, including archival observations, span two super-orbital periods. There is no evidence for a correlation between the TeV emission and the mass-loss rate of the Be star, but this may be affected by the strong, short-timescale (as short as intra-day) variation displayed by the H α fluxes.

Key words. astroparticle physics – binaries: general – gamma rays: general – stars: individual: LS I +61°303 – X-rays: binaries – X-rays: individuals: LS I +61°303

1. Introduction

LS I +61°303 (=V615 Cas) is a gamma-ray binary composed of a rapidly rotating Be star of spectral type B0Ve (Hutchings & Crampton 1981) with a circumstellar disk and a compact object of unknown nature. The compact object, either a neutron star (NS) or a stellar-mass black hole (BH),

has an eccentric orbit ($e = 0.54 \pm 0.03$) with a period of 26.4960(28) days, determined from radio observations (Gregory 2002). The periastron passage occurs at phase $\phi = 0.23 \pm 0.03$, although its precise timing depends on the orbital solution (Gregory 2002; Casares et al. 2005; Grundstrom et al. 2007; Aragona et al. 2009)¹.

LS I +61°303 is one of the few binary systems detected from radio to very high energy (VHE) gamma rays. The origin of the broadband emission is still under debate. LS I +61°303 was proposed as a microquasar, based on its extended jet-like radio-emitting structures, see Massi et al. (2004), for instance, and more recently, Massi & Torricelli-Ciamponi (2014). However, images obtained with the VLBA during a complete orbital cycle showed a rotating tail-like morphology of overall size 5–10 mas (Dhawan et al. 2006), consistent with a pulsar wind scenario (Maraschi & Treves 1981). Similar phase-resolved structures were later observed by Albert et al. (2008d). The source appears extended in X-rays (Paredes et al. 2007; Kargaltsev et al. 2014). Deep observations searching for X-ray pulsing have yielded only upper limits (Rea et al. 2010).

LS I +61°303 was first detected in the regime by MAGIC in 2006 (Albert et al. 2006). During the following years, more observations have been performed by the MAGIC (Albert et al. 2008d, 2009; Anderhub et al. 2009; Aleksić et al. 2012a) and VERITAS collaborations (Acciari et al. 2008). The VHE emission region is unresolved (<0.1 deg). The system is also a HE gamma-ray *Fermi*/LAT source (Abdo et al. 2009). Long-term monitoring shows that the HE emission undergoes periodic outbursts slightly after the periastron passage, around phases $\phi \sim 0.3$ – 0.45 (Hadasch et al. 2012). In the orbit from MJD 53 752.7 until MJD 53 779.2 (January–February 2006), a TeV peak was first detected at phases $\phi \sim 0.6$ – 0.7 (which correspond to the phases next to the apastron) at a level of $\sim 16\%$ of the Crab Nebula flux for energies above 400 GeV. However, in October 2009–January 2010, the source was in a low flux state (Aleksić et al. 2012a) and the emission peak was above 300 GeV with a flux of only 5.4% of the Crab Nebula. Despite the state of the system, the highest TeV flux also occurred at phases $\phi = 0.6$ – 0.7 , consistent with previous observations. The spectral fit parameters agreed with our previous determinations (Albert et al. 2008d, 2009; Anderhub et al. 2009). Significant emission has also occasionally been observed at phases $\phi = 0.8$ – 1 , where MAGIC detected the system at $\sim 4\%$ Crab Units (C.U.) (Albert et al. 2009). Emission around periastron has been reported once, by VERITAS, in late 2010 at phase $\phi = 0.081$ (Acciari et al. 2011) when the compact star was near superior conjunction.

Orbit-to-orbit variability has been associated with a super-orbital modulation. This was first proposed based on centimeter radio variations that show approximately sinusoidal modulation over 1667 ± 8 days (Paredes 1987; Gregory 2002). A similar long-term behavior has recently been suggested for X-rays (3–30 keV observed with RXTE; Li et al. 2012; Chernyakova et al. 2012), hard X-rays (18–60 keV observed with INTEGRAL; Li et al. 2014) and HE gamma-rays (100 MeV–300 GeV observed with *Fermi*/LAT; Ackermann et al. 2013). In the LAT energy range, the super-orbital variability is almost invisible around the periastron, where the compact object is inside (or highly affected by) the Be circumstellar disk, but appears around apastron.

Two short (<0.1 s) and very luminous ($>10^{37}$ erg s⁻¹) bursts have been detected from the direction of LS I +61°303

by the *Swift* Burst Alert Telescope (Barthelmy et al. 2008; Burrows et al. 2012). A detailed analysis of these events was presented by Torres et al. (2012), where their similarities to those observed from magnetars were analyzed. If the bursts are associated with the system, as it seems, it requires that the system harbors a neutron star and not a black hole.

The idea of a transitioning system, that is, a system that swings from one state to another at every orbital period, has been suggested by Zamanov et al. (2001). Torres et al. (2012) and Papitto et al. (2012) extended this to the super-orbital behavior and analyzed orbitally induced variability.

In this so-called flip-flop scenario, the system changes from propeller regime accretion at periastron, where the pulsar magnetosphere is disrupted, to an ejector regime (rotational-powered pulsar) at apastron, when particles are accelerated to TeV energies in the inter-wind shock formed at the collision region between the neutron star and the stellar wind. Despite the system differences, this would make LS I +61°303 similar to the transitional pulsars in redbacks, for example, Archibald et al. (2009) and Papitto et al. (2013).

Changing the Be star mass-loss rate can cause the switching from one state to the other to vary in orbital phase, modulated along the super-orbital timescale as measured by the equivalent width (EW) of the H α line, for instance. The sizes of the stellar disks of Be stars correlate with the EW of the H α emission line (e.g., see Porter & Rivinius 2003 and Reig 2011 for a review). Grundstrom & Gies (2006) also showed that the EW is correlated with the radius of the circumbinary disk, and therefore it can be used as a proxy of the latter. For times of high mass-loss rate, at which the influence of the disk matter upon the compact object can be felt along a greater portion of the orbit, the propeller regime can be operative even close to apastron. If this is the case, the TeV emission of LS I +61°303 would be reduced (Torres et al. 2012).

2. Observations

A campaign using the MAGIC telescopes together with the optical telescope was carried out over four years. Both instruments are located on the island of La Palma, in the Canary Islands, Spain, at the observatory of El Roque de Los Muchachos (28°N, 18°W, 2200 m above the sea level). The MAGIC telescopes are two Imaging Atmospheric Cherenkov Telescopes (IACTs) with diameters of 17 m, each one with a pixelized camera, covering a field of view of $\sim 3.5^\circ$. The current sensitivity of the stereoscopic MAGIC telescopes is $0.71\% \pm 0.02\%$ of the Crab Nebula flux in 50 h of observation for energies above 250 GeV (Aleksić et al. 2015). The angular resolution at these energies is $\lesssim 0.1^\circ$ (68% containment radius) and the energy resolution is $\sim 18\%$. For monoscopic observations (also referred to as mono-observations) the integral sensitivity above 280 GeV is about 1.6% of the Crab Nebula flux in 50 h (Aliu et al. 2009). The observations were carried out in wobble mode, pointing at two different symmetric regions situated 0.4° away from the source position to simultaneously evaluate the background (Fomin et al. 1994).

The data were analyzed using the standard MAGIC analysis and reconstruction software, MARS (Zanin et al. 2013). The recorded images were calibrated, cleaned, and parametrized (Hillas 1985; Albert et al. 2008a). The background rejection and the estimation of the gamma-direction was performed using the Random Forest (RF) method (Albert et al. 2008b). The energy of each event was estimated using look-up tables generated by Monte Carlo simulations (Aleksić et al. 2012b). For

¹ Here, the reference for the periastron passage is taken at $T_0 = 43\,366.275$ MJD (Gregory 2002).

58	56 920.1–56 930.1	0.54–0.92	0.13	20.72	10

Notes. The first column denotes the orbit number, the second column indicates the dates of the observation, the third and fourth columns display the orbital and super-orbital phases, while the fifth and sixth columns indicate the integration time and its distribution, respectively.

mono-observations, the event direction and energy of the primary gamma ray were also reconstructed with the RF method.

The LIVERPOOL robotic telescope is an optical telescope that is also located on La Palma. Its instrument, FRODOSpec, provides spectra with $R \sim 5500$ resolution simultaneously in the blue and red spectral ranges. The red spectrum includes the $H\alpha$ line, which we used as the prime indicator of the Be circumstellar disk through the equivalent width (EW), full width at half maximum (FWHM), and centroid velocity, the latter two obtained through a single Gaussian fit to the emission profile.

LS I +61°303 was observed between August 2010 and September 2014. All data were obtained with the MAGIC stereoscopic system, except for January 2012, when MAGIC-I was inoperative. The source was observed during the orbital range $\phi = 0.5\text{--}0.75$ to observe the complete trend of the periodical outburst peak of the TeV emission, with the aim of detecting a putative long-term modulation. Contemporaneous observations with MAGIC and LIVERPOOL were performed during orbital phases $0.75\text{--}1.0$, which are the phases where sporadic VHE emission had been detected and which does not seem to present yearly periodical variability of the flux level (Aleksić et al. 2012a). Since the fluxes in this orbital period are not influenced by the long-term modulation, changes in the relative optical and TeV fluxes are larger and easier to measure. The aim of these contemporaneous observations is to search for (anti-)correlation between the mass-loss rate of the Be star and the TeV emission. The details of the observations in an orbit-to-orbit basis are summarized in Table 1.

3. Results

3.1. Spectral stability

LS I +61°303 has shown variability on timescales of years in the strength of its periodic outburst peaks. To understand if the mechanism producing gamma rays is the same, independent of the flux of the source and its super-orbital state, it is interesting to search for spectral variability as a function of time. The VHE spectrum for the complete observed data set (see Table 2) can be

Notes. The first column indicates the campaign name, the second the orbital range where the SED was computed, the third the average super-orbital phase of the campaign, and the fourth the spectral index with its corresponding statistical and systematic uncertainties.

Fig. 1. Super-orbital dependence of the spectral index α for all MAGIC campaigns of LS I +61°303, considering a 1667-day period. The blue line corresponds to the average value.

described as

$$\frac{dN_\gamma}{dAdt dE} = N_0 \left(\frac{E}{E_0} \right)^\alpha, \quad (1)$$

with $N_0 = (4.4 \pm 0.1_{\text{stat}} \pm 0.2_{\text{sys}}) \times 10^{-13} \text{ TeV}^{-1} \text{ cm}^{-2} \text{ s}^{-1}$, $\alpha = -2.4 \pm 0.2_{\text{stat}} \pm 0.2_{\text{sys}}$ and the normalization energy $E_0 = 1 \text{ TeV}$.

Table 3 collects the spectral indices for each of the observational campaigns. They are all similar within systematic errors. In 2011, a hardening was observed, but with low statistical significance. It was not confirmed by later observations. Therefore, we can conclude that the VHE spectrum is consistent with a single power-law during different epochs.

The dependence of α on phase with the 1667 day super-orbital period is shown in Fig. 1. The data can be fit to a constant value of 2.43 ± 0.04 ($\chi^2/\text{d.o.f.} = 8.9/7$).

We divided the dataset into intervals of high (defined as the flux being at 5–10% of the Crab Nebula flux) or low (flux at 2–5% of the Crab Nebula flux) activity. We also separated the data depending on the orbital interval of the emission into a periodical ($\phi = 0.5\text{--}0.75$) interval, where the periodic TeV outburst occurs, and a sporadic ($\phi = 0.75\text{--}1.0$) interval, where significant emission has been detected sporadically in the past. In neither case does the spectral index vary significantly. Fitting the

data with a constant α results in an average value of 2.4 ± 0.1 ($\chi^2/\text{d.o.f.} = 0.90/2$) with a probability of 0.83.

3.2. Super-orbital modulation

We performed a search for indications of a super-orbital flux modulation using the peak flux measurements at orbital phases $\phi = 0.5\text{--}0.75$. However, some of the system's emission peaks may have been missed, for instance, because observations can only be performed once every 24 h and because some nights were lost because of bad weather or technical problems. To minimize this effect, we only selected those measurements for which at least three consecutive observations in the requisite phase interval were successful and for which the middle time shows a higher flux than the others.

We justified this approach by simulating exactly this situation. Since observations can only be performed once every 24 h, a maximum in emission from the binary system may be missed. Additionally, observations were also lost during intervals of bad weather or technical problems. To minimize the effects of missing the maximum emission during any cycle, we only considered those orbits for which observations occurred during at least three consecutive nights in the specific phase interval. We also required that the middle observation showed the highest flux. By further assuming a shape (Landau distribution) similar to the one observed in Anderhub et al. (2009), we then calculated the percentage deviation between the actual maximum of the emission and the assigned value of the maximum. We checked that at one sigma, the difference between the estimated maximum flux level and the actual maximum was smaller than <35%, while this value increased to 90% if the maximum was used, even requiring three consecutive nights. This estimate allowed us to study the dependence of the amplitude on the orbital periodic emission observed at VHE with time.

All archival data of LS I +61°303 recorded by MAGIC since its detection in 2006 (Albert et al. 2008d, 2009; Anderhub et al. 2009; Aleksić et al. 2012a) and the data from the observing campaigns presented were folded onto the superorbital period of 1667 days. We considered statistical and systematic uncertainties in the integrated flux: 12% systematics for stereo data, according to Aleksić et al. (2012b), and 15% systematics for mono data, estimated from Albert et al. (2008c). We augmented our sample using the many observations made by VERITAS of LS I +61°303, that is, Acciari et al. (2008, 2009, 2011) and Aliu et al. (2013), using the same procedure to identify the peak of emission. We assumed 20% systematic uncertainties (Griffin 2014) that were added quadratically to the corresponding statistical uncertainties.

The temporal evolution of the peak-integrated flux above 300 GeV for each orbit is presented in Fig. 2. Folded light-curve data were fit by first assuming a hypothesis of a constant flux, and secondly assuming a sinusoidal function. The fit to a sine function yielded a period of 1610 ± 58 days with a probability of 6% ($\chi^2/\text{d.o.f.} = 26.6/17$). Since the fit probability for a constant fit is much lower, with 4.5×10^{-12} ($\chi^2/\text{d.o.f.} = 114.8/20$), we can conclude that the TeV flux is variable along the superorbit and that a sinusoidal behavior with a period of 1610 days is preferred over a constant one.

Figure 3 shows the same data, but folded onto the super-orbital period of 1667 days. Here the data were fit not only with a constant and a sinusoidal, but also to two-emission levels (step function):

$$f(x) = \begin{cases} a & \text{if } p_1 < x < p_2, \\ b & \text{if } x < p_1 \text{ \& } x > p_2, \end{cases}$$

Fig. 2. Temporal evolution of the peak of the VHE emission for each orbital period in terms of the MJD. MAGIC (magenta dots) and VERITAS (blue squares) data within orbital phases 0.5–0.75 have been considered. The gray dashed line represents 10% of the Crab Nebula flux, the gray solid line the zero level. The fit with a sinusoidal is plotted in red and the fit with a constant in blue.

Fig. 3. Peak of the VHE emission in terms of the super-orbital phase defined in radio. Each data point represents the peak flux emitted in one orbital period during orbital phases 0.5–0.75 and is folded into the super-orbit of 1667 days known from radio observations (Gregory 2002). MAGIC (magenta dots) and VERITAS (blue squares) points have been used in this analysis. The fit with a sinusoidal (solid red line), with a step function (solid green line), and with a constant (solid blue line) are also represented. The gray dashed line represents 10% of the Crab Nebula flux, the gray solid line the zero level for reference.

where a , b , p_1 , and p_2 are the free parameters of the fit. The results of the different fits are presented in Table 4. The probability for a constant flux is negligible, 4.5×10^{-12} . Assuming a sinusoidal signal, the fit probability reaches 8% ($\chi^2/\text{d.o.f.} = 27.2/18$). The fit to a step function resulted in a fit probability of 7% ($\chi^2/\text{d.o.f.} = 26.4/17$). We furthermore quantified the probability that the improvement found when fitting a sinusoid or a step function instead of a constant is produced by chance. To obtain this probability, we considered the likelihood ratio test (Mattox et al. 1996). In both cases this chance probability is $< 2.5 \times 10^{-10}$, which is low. This shows that the observed intensity distribution can be described by a high and a low state and with a smoother transition. We conclude that there is a super-orbital signature in the TeV emission of LS I +61°303 and that

Table 4. Fitting functions with the corresponding fit probabilities for MAGIC + VERITAS data of LS I +61°303 folded into the superorbit (Fig. 3).

Function	Fit probability	$\chi^2/\text{d.o.f.}$
Constant	4.5×10^{-12}	114.8/20
Step function	0.07	26.4/17
Sinusoidal	0.08	27.2/18

Table 5. Correlations between the TeV flux obtained by MAGIC and the $H\alpha$ parameters (EW, FWHM, and vel) measured by LIVERPOOL for the extended orbital interval 0.75–1.0.

Simultaneity	Parameters	r	Prob
Nightly	TeV–EW	–0.51	0.04
Nightly	TeV–FWHM	–0.22	0.27
Nightly	TeV–vel	–0.38	0.11
Contemporary (hourly)	TeV–EW	–0.14	0.37
Contemporary (hourly)	TeV–FWHM	–0.44	0.16
Contemporary (hourly)	TeV–vel	–0.21	0.35

Notes. Only TeV data with a significance higher than 1σ have been considered. The first column indicates the level of simultaneity of the observations, the second column shows the parameters we used to search for a correlation, and the third and fourth columns give the Pearson correlation coefficient and the associated probability for a non-correlation.

it is compatible with the 4.5-year radio modulation seen in other frequencies.

3.3. Simultaneous optical-TeV observations

The correlation between the TeV flux measured by MAGIC and the $H\alpha$ parameters measured with the telescope (EW, FWHM, profile centroid velocity) were determined including statistical and systematic uncertainties and the weighted Pearson correlation coefficient (Soper et al. 1917).

To search for correlations, we classified the data into three different categories:

- *Simultaneous*: the optical observations were performed precisely during the period when MAGIC was performing its observations. Only three such points were obtained under this condition. Because of the scarcity of such data we do not provide any correlation coefficient for this group.
- *Contemporary (hourly)*: data have a time difference of three hours at most.
- *Nightly*: data were obtained during the same night.

Only TeV data points with a significance higher than 1σ were considered.

The data used for the correlation are given in Table 5. No statistically significant correlation was found for the sample at orbital phases $\phi = 0.75$ –1.0. A hint of a correlation is observed, but its significance is low. A stronger correlation might be blurred as a result of the fast variability of the optical parameters on short timescales compared to the long exposure times required by MAGIC, and as a result of the relatively large uncertainties and small number of data points used for this analysis. Figure 4 shows the $H\alpha$ measurements plotted against the TeV flux.

Fig. 4. Correlations between the TeV flux obtained by MAGIC and the $H\alpha$ parameters (from top to bottom: EW, FWHM, and centroid velocity (vel)) measured by the LIVERPOOL Robotic Telescope for the orbital interval 0.75–1.0. Only TeV data points with a significance higher than 1σ have been considered. Each data point represents a ten-minute observation in the optical and a variable integration in the TeV regime: nightly (blue), contemporary (red), and strictly simultaneous data (green). Black error bars represent statistical uncertainties, while systematic uncertainties are plotted as magenta error bars.

4. Discussion and conclusion

The main conclusions from this multi-year analysis of LS I +61°303 TeV observations are listed below.

1. We achieved a first detection of super-orbital variability in the TeV regime. Using the new VHE data and the MAGIC and VERITAS archival data, we found that the super-orbital signature of LS I +61°303 is consistent with the 1667-day radio period within 8%. The TeV period obtained when fitting the data to a sine function with a free frequency instead of performing the fit as before with a fixed super-orbital period known from radio, is 1610 ± 58 days with a fit probability of 6%.
2. There is no statistically significant intra-day correlation between $H\alpha$ line properties and TeV emission, nor is there an obvious trend connecting the two frequencies.

The flip-flop model (Zamanov et al. 2001; Torres et al. 2012; Papitto et al. 2012) considers LS I +61°303 as a pulsar-Be star binary that changes accretion states from a propeller regime during periastron to an ejector regime at apastron. The change of state is thought to be driven by the influence of matter. The

higher the pressure of this matter on the (hypothesized) neutron star magnetosphere, the more likely the latter will be compressed and disrupted. When this occurs, the pulsar wind is affected or disappears, and the inter-wind shock, which is thought to contribute to the multi-frequency non-thermal emission, disappears as well. Even when the neutron star passage at periastron is able to cut the disk off, mass accumulation will be higher in periods in which the decretion rate is higher, reaching farther out in the orbit. A larger EW of $H\alpha$ may be assumed as a proxy for such a situation. If this is the case, the optical emission should be anti-correlated with the TeV flux. The detection of TeV gamma-ray super-orbital emission conforms to the predicted long-term behavior of the flip-flopping model (Torres et al. 2012). The source was found in high and low states, when expected. This result extends the earlier indications for this phenomenology found using smaller samples of TeV data (Li et al. 2012). However, we do not see this (anti-) correlation in the intra-day scales we tested. It may be that the EW of $H\alpha$ is not the best tracer for decretion disk size or mass accumulation, or simply that the fast and extreme changes (by up to a factor of several in the same day) in the $H\alpha$ data of the source and the vastly different integration times (minutes as compared with several hours) needed to claim a detection in both frequencies prevent us from measuring any possible trend.
