Abstract

We present a study of the γ -ray emission detected by the Astrorivelatore Gamma ad Immagini LEggero-Gamma Ray Imaging Detector (*AGILE*-GRID) from the region of the SNR G78.2+2.1 (Gamma Cygni). In order to investigate the possible presence of γ rays associated with the SNR below 1 GeV, it is necessary to analyze the γ -ray radiation underlying the strong emission from the pulsar PSR J2021+4026, which totally dominates the field. An “off-pulse” analysis has been carried out, by considering only the emission related to the pulsar off-pulse phase of the *AGILE*-GRID light curve. We found that the resulting off-pulsed emission in the region of the SNR—detected by the *AGILE*-GRID above 400 MeV—partially overlaps the radio shell boundary. By analyzing the averaged emission on the whole angular extent of the SNR, we found that a lepton-dominated double-population scenario can account for the radio and γ -ray emission from the source. In particular, the MeV–GeV averaged emission can be explained mostly by Bremsstrahlung processes in a high density medium, whereas the GeV–TeV radiation can be explained by both Bremsstrahlung ($E_\gamma \lesssim 250$ GeV) and inverse Compton processes ($E_\gamma \gtrsim 250$ GeV) in a lower density medium.

Key words: acceleration of particles – cosmic rays – gamma rays: ISM – gamma rays: stars – ISM: supernova remnants

1. Introduction

The radio source G78.2+2.1 (Gamma Cygni) is a typical shell-type supernova remnant (SNR) located within the extended emission of the Cygnus X region (Piddington & Minnett 1952).

During 70 s, observations in the Cygnus X direction showed the presence of nonthermal emission from this source (Wendker 1970; Higgs 1977) and then Higgs et al. (1977), with a study based on arcmin resolution observations at 1.42 GHz with the Dominion Radio Astrophysical Observatory (DRAO), confirmed the nature of this object: an SNR, with a shell structure of $\sim 62'$ diameter, located at $(l, b) = (78.2, 2.1)$. The inferred distance of the SNR is $d = 1.5$ kpc $\pm 30\%$ (Landecker et al. 1980) and the corresponding shell radius is $R \simeq 13.5$ pc. By analyzing X-ray data from the Advanced Satellite for Cosmology and Astrophysics (ASCA), Uchiyama et al. (2002) observed a region (R3) with an arclike morphology along the outer boundary of the radio spherical shell emitting thermal radiation with $kT_e = 0.76_{-0.09}^{+0.10}$ keV. This feature indicates the presence of a thin thermal plasma in the SNR post-shock region propagating through the interstellar medium. Assuming a strong shock scenario, they inferred a shock velocity $v_s = 800_{-60}^{+50}$ km s⁻¹ in the light of the relation with the electron temperature. Provided that the SNR is in the Sedov adiabatic expansion phase, they estimated the age of G78.2+2.1, $\tau_{\text{age}} \simeq 6600$ yr. Moreover, they reported the discovery of some clumps (in the northwestern (NW) part of the SNR) with a hard power-law tail ($\Gamma \sim 0.8$ – 1.5) spectral component (3–8 keV), possibly related to nonthermal Bremsstrahlung and indicating a shock-cloud interaction.

Ladouceur & Pineault (2008) studied this SNR very extensively, by analyzing radio continuum emission at 408

and 1420 MHz, radio 21 cm line emission of HI, infrared continuum emission at $8.23 \mu\text{m}$ and $60 \mu\text{m}$. They found that the SNR nonthermal synchrotron emission has a quasi-perfect circular shape remarking its spherical symmetry. Furthermore, they analyzed the HI kinematics leading to a model of the SNR dynamical evolution through the surrounding gas. The most probable scenario suggests that the SNR progenitor would have largely evacuated a cavity around the star through a strong stellar wind. An expanding shell of HI has been set in motion by this wind with an expanding velocity of a few km s⁻¹.

The first γ -ray source ever associated to the SNR G78.2+2.1 was 2CG 078+2, detected by the COS B satellite (Pollock et al. 1985). They detected a γ -ray source centered at $(l, b) = (78.1, 2.3)$ with a photon flux above 300 MeV of about $F_\gamma \approx 4.8 \cdot 10^{-8}$ photons cm⁻² s⁻¹. Pollock (1985) proposed a probable association with the SNR, based on the spatial coincidence of the γ -ray source with a bright radio feature (DR4; Downes & Rinehart 1966) and a molecular cloud near the remnant (source number 8 in the CO survey of the Cygnus X region by Cong 1977). According to the author’s interpretation, γ rays are produced by Bremsstrahlung emission from accelerated electrons in correspondence with molecular cloud/shock interaction.

Nevertheless, the association with the SNR remained doubtful. In fact, the EGRET associated γ -ray source, 3EG J2020+4017, was presented as the brightest unidentified point source in the third EGRET Catalog (Hartman et al. 1999). It is located at $(l, b) = (78.05, 2.08)$, with a 95% C.L. error box of $0^\circ.16$ and a photon flux above 100 MeV of $F_\gamma = (123.7 \pm 6.7) \cdot 10^{-8}$ photons cm⁻² s⁻¹.

The Astrorivelatore Gamma ad Immagini LEggero-Gamma Ray Imaging Detector (*AGILE*-GRID, Barbiellini et al. 2002; Prest et al. 2003; Tavani et al. 2009) observations found that

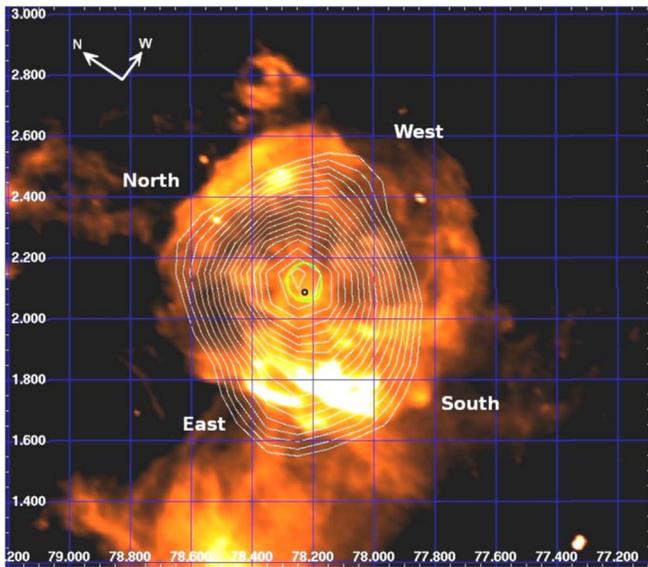

Figure 1. Gamma Cygni SNR (G78.2+2.1) in Galactic coordinates. Image obtained with the Dominion Radio Astrophysical Observatory (DRAO), from the Canadian Galactic Plane Survey (CGPS), wavelength = 21.1 cm (frequency = 1420 MHz, bandwidth = 30 MHz), pixel size = 20" (Taylor et al. 2003). White contour levels: *AGILE*-GRID intensity contour levels above 100 MeV—related to data integrated between 2007 November 2 and 2009 July 29—(pixel size 0".1), starting from 0.00085 in steps of 0.00002 (intensity per pixel); green contour: *AGILE*-GRID 95% confidence level for $E \geq 100$ MeV; black circle: PSR J2021+4026. Orientation of the Celestial coordinates is marked.

the corresponding source, 1AGL J2022+4032 (Pittori et al. 2009), has a position and a γ -ray photon flux above 100 MeV consistent with the EGRET values. We found a bright point source within a widespread γ -ray emission morphologically consistent with the circular shape detected at radio wavelengths (see Figure 1). 1AGL J2022+4032 is a puzzling γ -ray source, showing some hints of variability and it is likely to be a superposition of multiple point-like sources emitting in γ rays (see Chen et al. 2011).

Fermi-LAT (Atwood et al. 2009) has identified this source as the bright γ -ray pulsar PSR J2021+4026 (3FGL J2021.5+4026, Abdo et al. 2009, 2010a, 2010b, 2013; Acero et al. 2015), characterized by a sharp exponential cutoff at $E = (2.37 \pm 0.06)$ GeV. The *Fermi*-LAT observations found a significant decrease in flux (for $E > 100$ MeV) from this pulsar around mid-2011 October, with a simultaneous increase in the frequency spindown rate (Allafort et al. 2013). The X-ray counterpart of PSR J2021+4026 is 2XMM J202131.0+402645 (Trepl et al. 2010; Weisskopf et al. 2011), whose pulsations were discovered in the X-ray band and reported by Lin et al. (2013). No radio pulsations have been detected so far from this source.

Above 10 GeV, *Fermi*-LAT detected a significant extended source that is consistent with the spherical shell of the SNR detected at radio wavelengths (Lande et al. 2012; Ackermann et al. 2017). Furthermore, a bright γ -ray excess is detected in the NW rim of the remnant at GeV (*Fermi*-LAT; Fraija & Araya 2016) and TeV energies (VERITAS, Aliu et al. 2013; Abeysekara et al. 2018), VER J2019+407 (see Figure 4). SNR G78.2+2.1 was included in the first *Fermi*-LAT SNR catalog, a survey ranging from 1 to 100 GeV (Acero et al. 2016).

Therefore, in this region the overall γ -ray emission between 100 MeV and a few GeV is totally dominated by the strong

pulsar, with the high-energy emission from the SNR only accounting for an underlying component of the field. In order to evaluate the presence of diffuse high-energy emission correlated to the SNR, we analyzed the emission in the field within the off-pulse interval of the bright pulsar PSR J2021+4026.

2. Data Analysis

The *AGILE* satellite was launched on 2007 April 23. Until 2009 October it worked in “pointing” mode with fixed attitude, and from 2009 November it operates in “scanning mode”, with a controlled rotation of the pointing axis. During the “pointing” mode data-taking (~ 2.5 yr) the *AGILE* satellite performed ~ 100 pointings, called Observation Blocks with variable exposure times (typically 3–30 days), drifting about 1° per day with respect to the initial boresight direction to match solar panel illumination constraints.⁷ In this configuration the *AGILE*-GRID was characterized by enhanced performances in the monitoring capability of a given source, especially in the energy band 100–400 MeV (see Bulgarelli et al. 2012 for details). The Cygnus region was one of the preferred targets of the *AGILE* pointing plan. Thus, we were able to obtain a deep exposure of this sky region already in the relatively short pointing phase.

In this paper we present an analysis of this region on a deep integration of the *AGILE*-GRID data from 2007 November 2 to 2009 July 29 (the same data set reported by Chen et al. 2011; Piano et al. 2012). During this period *AGILE* repeatedly pointed at the Cygnus region for a total of ~ 275 days, corresponding to a net exposure time of ~ 11 Ms. The analysis was carried out by using the last available *AGILE*-GRID software package (Build 25), FM3.119 calibrated filter, I0025 response matrices, and consolidated archive (ASDCe) from ASI Data Center.

In order to investigate the presence of γ rays produced by the SNR shock, we tried to unveil the emission underlying the pulsar dominating radiation, by performing an “off-pulse” analysis (Pellizzoni et al. 2010).

The pulsar ephemeris we used was obtained from the *Fermi*-LAT data. Because PSR J2021+4026 is known to be variable (Allafort et al. 2013), we selected an interval as close as possible to our observations (2008 June to 2009 May) and well before the “jump,” which was observed by Allafort et al. (2013) in 2011 October. Given the *AGILE* pointing observing strategy, further addition of pointing data did not provide a significant improvement in the statistics and significance of the detection. Thus, we decided to keep the same interval as in Chen et al. (2011) for consistency. We decided to not extend the solution to the scanning mode data set, because even if it keeps the imaging accuracy (Piano et al. 2017, 2018), it does not improve the analysis of the timing profile. This is probably due to instabilities in the pulsating emission of the source during this period.

Based on the pulsed signal analysis described in Pellizzoni et al. (2009), we selected only high confidence γ -ray photons (G) with energy above 100 MeV within a radius of 1 degree from the pulsar position (R.A.: $20^{\text{h}} : 21^{\text{m}} : 30^{\text{s}}.733$, decl.: $+40^\circ : 26' : 46''.04$) (J2000, Weisskopf et al. 2011) so as to avoid contamination from the nearby crowded environment. We

⁷ A detailed schedule of the *AGILE* Observation Block is available online at http://agile.asdc.asi.it/current_pointing.html.

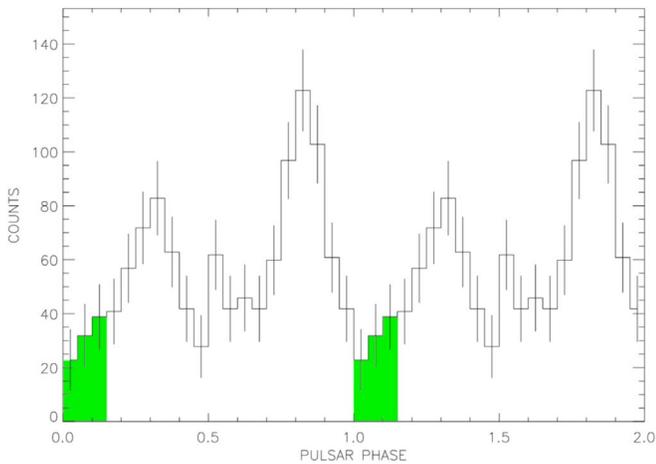

Figure 2. *AGILE*-GRID folded light curve of PSR J2021+4026, photons with $E > 100$ MeV, 2 cycles with 20 bins per cycle. The green regions highlight the off-pulse phase, $0.00 \leq \Delta\phi \leq 0.15$, adopted in this analysis.

performed a first folding over the nominal period and period derivative ($P = 0.26531701593(3)$ s, $\dot{P} = 5.483(3) \times 10^{-14}$), producing a detection at 4σ . Because the ephemeris did not fully cover the data interval, we also chose to perform a 5σ search around the nominal period in order to fully exploit *AGILE*'s temporal resolution resulting from the long observing time span. We found that the best period for this interval is $P = 0.26531701607(9)$ s, with a weighted post-trial detection significance of 5.3σ . The *AGILE*-GRID light curve folded on the corresponding period of the PSR J2021+4026 is shown in Figure 2.

The pulsed profile of PSR J2021+4026 is not the common double-peaked γ -ray profile of many energetic γ -ray pulsars: it is characterized by a high unpulsed fraction and a not sharp separation between on-peak and off-peak phases. Thus, the *AGILE*-GRID off-pulse profile for this object was quite complex to determine. We decided to adopt, as the best-defined off-pulse phase, the phase interval $0.00 \leq \Delta\phi \leq 0.15$ (green-highlighted region in Figure 2).

In Figure 3 the *AGILE*-GRID intensity map related to the off-pulse interval ($0.00 \leq \Delta\phi \leq 0.15$, green band in Figure 2) is compared to the map related to the secondary peak interval ($0.25 \leq \Delta\phi \leq 0.40$). We note that, whereas in the latter, the pulsar is still bright and dominates the field, in the former, a weaker pulsar remnant is detected together with a diffuse emission in the southeastern (SE) rim of the shell. The off-pulse image above 400 MeV shows a complex extended-source morphology.

The imaging of the SNR region has been analyzed above 400 MeV (Figure 4), considering the γ -ray emission weighted on the residual 15% exposure time. We decided to investigate the imaging profile above 400 MeV (and not above 100 MeV) because of a better *AGILE*-GRID point-spread function (PSF) at those energies (4.2 at 100 MeV, 1.2 at 400 MeV, 68% containment radius, Sabatini et al. 2015). In doing so, we can better investigate the correlation with other wavelengths.

In Figure 5 the *AGILE*-GRID contours of the off-pulse intensity map above 400 MeV are superimposed on the radio map (wavelength = 21.1 cm) of the SNR. If the emission underlying the intense γ -ray radiation from the pulsar is unveiled, an extended and complex γ -ray morphology comes out, presumably correlated to the SNR. The γ -ray emission shape within the SNR shell partially covers the boundary of the

remnant in coincidence with a bright SE feature (DR4, Downes & Rinehart 1966) of the radio synchrotron shell (see the *AGILE*-GRID contour levels in Figure 5).

Finally an extended-source multisource likelihood analysis (MSLA, multi version of the *AGILE*-GRID software package) was carried out on the off-pulse map above 400 MeV, taking into account the emission from the three Cygnus γ -ray pulsars (PSR J2021+4026, PSR J2032+4127, and PSR J2021+3651). In order to account for the reduced exposure, the photon flux values for these persistent objects have been set as free parameters in the multisource analysis and reestimated. First, we estimated the photon fluxes of the distant pulsars: PSR J2021+3651 and PSR J2032+4127. Second, we kept the spectral parameters fixed for those pulsars to the ones found in the first step and analyzed the SNR together with the pulsar PSR J2021+4026. Our MSLA software (Bulgarelli et al. 2012) is based on the Test Statistic (TS) method as formulated by Mattox et al. (1996). This statistical analysis provides a detection significance assessment of a γ -ray source by comparing maximum-likelihood values of the null hypothesis (no source in the model) with the alternative hypothesis (point or extended source in the field model).

In order to perform an extended-source analysis, we adopt the radio quasisymmetrical shell properly convolved with the *AGILE*-GRID PSF above 400 MeV as template for the maximum-likelihood study (see Figure 6). We found a detection significance of $\sqrt{\text{TS}} = 8.6$ and a flux $f(E > 400 \text{ MeV}) = (14.8 \pm 2.2) 10^{-8}$ photons $\text{cm}^{-2} \text{s}^{-1}$. The remnant of the PSR J2021+4026 is weakly detected ($\sqrt{\text{TS}} \simeq 2$) with a flux $f(E > 400 \text{ MeV}) = (7.1 \pm 3.2) 10^{-8}$ photons $\text{cm}^{-2} \text{s}^{-1}$.

Furthermore, we carried out a spectral analysis between 100 MeV and 3 GeV, still assuming the same extended-source template, convolved with the corresponding PSF of each energy band. The results of this analysis are shown in Table 1 and Figure 7, where the spectrum associated with the SNR (as calculated in this paper) is compared with the *AGILE* spectrum of the pulsar PSR J2021+4026 (2AGL J2021+4029, as presented in the Second *AGILE* catalog, Bulgarelli et al. 2019). We note that the pulsar is characterized by a harder spectrum with respect to the SNR. From the folded light curve of Figure 2, we expect a subdominant contamination of the pulsar remnant in the off-pulse data set.

3. Multiwavelength Imaging

In this section we present the multiwavelength emission in the SNR region. First, we considered the gas distribution, being the target of the accelerated high-energy particles and then we evaluated the pattern of the high-energy emission, from X-rays to VHE γ rays.

3.1. Gas Distribution

Assuming that CO and dust are good tracers of gas, we can estimate the pattern of the gas distribution by CO line emission and IR emission from the dust. The ^{13}CO ($J = 1 \rightarrow 0$) line emission from the Five College Radio Astronomy Observatory (FCRAO) survey, related to a positive velocity integration (0 to 20 km s^{-1}), shows a nearly empty region within the whole SNR extent (central panel in Figure 8). Interestingly, the negative velocity integration map (-20 to 0 km s^{-1} , left panel in Figure 8) shows a dense cloud that partially overlaps the

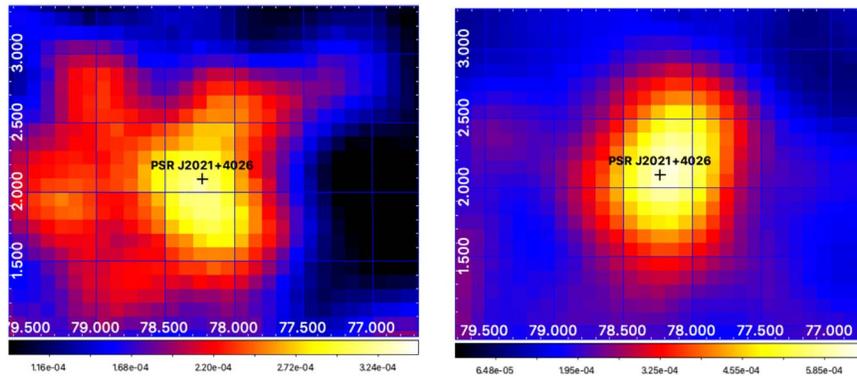

Figure 3. *AGILE*-GRID intensity maps above 400 MeV. Pixel size = $0\text{.}^{\circ}1$ with 5-pixel Gaussian smoothing, color bar scale in units of photons $\text{cm}^{-2} \text{s}^{-1} \text{pixel}^{-1}$. The black crosses mark the position of the pulsar PSR J2021+4026. Left panel: intensity map related to the off-pulse interval ($0.00 \leq \Delta\phi \leq 0.15$, green band in Figure 2). Right panel: intensity map related to the phase interval $0.25 \leq \Delta\phi \leq 0.40$.

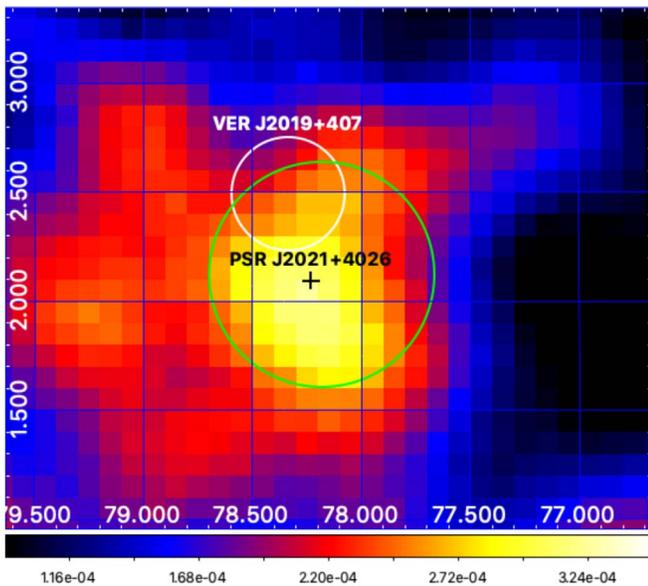

Figure 4. *AGILE*-GRID off-pulse (phase: 0.00–0.15) intensity map above 400 MeV of the Gamma Cygni SNR. Pixel size = $0\text{.}^{\circ}1$ with 5-pixel Gaussian smoothing, color bar scale in units of photons $\text{cm}^{-2} \text{s}^{-1} \text{pixel}^{-1}$. The black cross marks the position of the pulsar PSR J2021+4026. The green circle marks the extent of the SNR synchrotron shell as visible at radio wavelengths. The white circle marks the position of the extended TeV source, VER J2019+407, as detected by VERITAS (Aliu et al. 2013).

AGILE-GRID γ -ray diffuse emission along the SE rim of the shell. If we refer to the gas velocity distribution in the Local Arm inferred from HI kinematics (Ladouceur & Pineault 2008), this cloud—having a negative velocity range—could represent an approaching concentration of gas located in the surroundings of the SNR.

The IR image (right panel of Figure 8) shows the cosmic dust distribution in the SNR angular region. This is an image in the $8.23 \mu\text{m}$ wavelength (*MSX*, band A) of the region; this band may contain continuum thermal emission from dust at $\sim 400 \text{ K}$ (Ladouceur & Pineault 2008). We can notice an arclike structure (extending from $\sim(78.0, 2.0)$ to $\sim(78.4, 2.7)$) and a feature, located southeast of the synchrotron shell, associated by Ladouceur & Pineault (2008) to a similar thermal feature visible at radio wavelengths (see Figure 5). It is interesting to note that this hotspot is spatially consistent also with a bright γ -ray excess detected by the *AGILE*-GRID above 400 MeV.

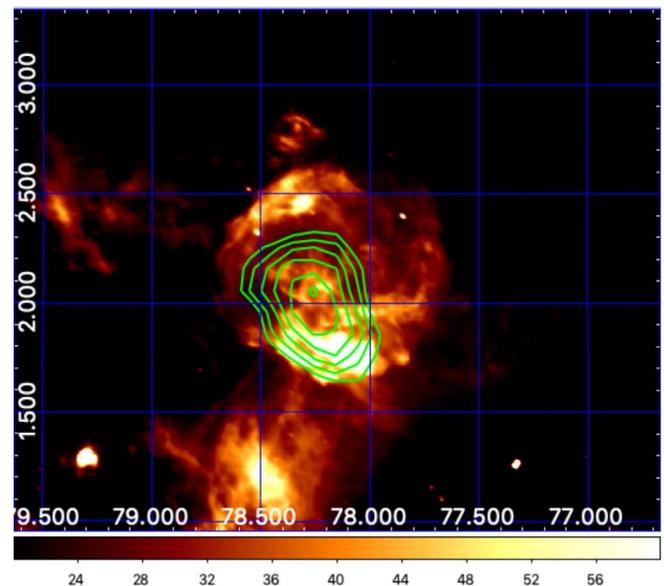

Figure 5. Radio image of the SNR G78.2+2.1 at 21.1 cm wavelength (frequency = 1420 MHz, bandwidth = 30 MHz), pixel size = $20''$, DRAO Radio Telescope. Overlaid are the *AGILE*-GRID contour levels (green), related to the off-pulse intensity map above 400 MeV.

3.2. High Energy Imaging: X-Ray, HE, and VHE γ Rays

By analyzing the X-ray data from ASCA, Uchiyama et al. (2002) found that, at energies below 3 keV, the bulk of the X-ray flux from the SNR can be well described by thermal emission from a plasma with a temperature of $kT_e \simeq 0.5\text{--}0.9 \text{ keV}$. In addition there is an extremely hard X-ray component from several clumps located in the NW part of the SNR. They found that this unusually hard spectra can be naturally interpreted with electron nonthermal Bremsstrahlung emission.

In the same region of the shell a bright source, VER J2019+407, is visible above 10 GeV by *Fermi*-LAT (Fraija & Araya 2016; Ackermann et al. 2017) and at TeV energies by VERITAS (Aliu et al. 2013; Abeysekara et al. 2018). This high-energy feature is consistent with the NW bright excess of the radio synchrotron shell.

On the other hand, *AGILE* detected a different morphology of the emission above 400 MeV, consistent with SE bright feature of the radio shell (DR4, see Figure 5). Nevertheless, in order to have a more conservative approach, taking into

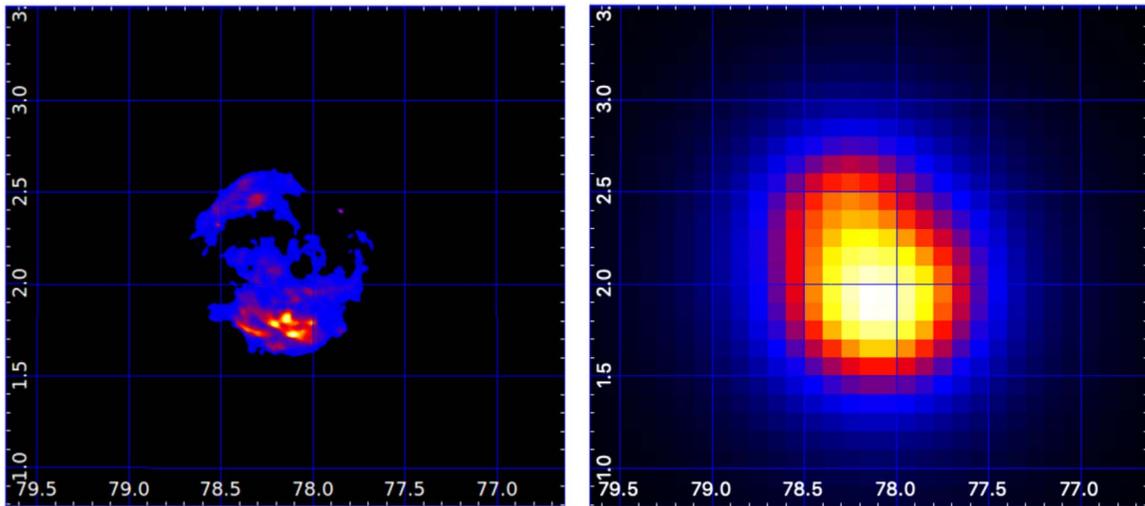

Figure 6. Left panel: radio emission related to the quasisymmetrical synchrotron shell in Galactic coordinates. Right panel: the same map convolved with the *AGILE*-GRID PSF above 400 MeV, and used as a template for the extended-source MSLA. The convolved template has a 68% containment radius of $\sim 1^\circ$.

Table 1

Spectrum of the SNR G78.2+2.1, as Detected by *AGILE*: Energy Band, Significance of Detection ($\sqrt{\text{TS}}$), Flux, and Radius of the SNR Template Convolved with the *AGILE* PSF (68% Containment Radius)

Energy Band (MeV)	$\sqrt{\text{TS}}$	Flux (10^{-8} photons cm^{-2} s^{-1})	Template Radius (degrees)
100–200	6.14	44.9 ± 7.9	~ 3.5
200–400	7.22	23.3 ± 3.7	~ 1.9
400–1000	7.07	11.6 ± 2.1	~ 1.1
1000–3000	3.80	2.2 ± 0.8	~ 0.7

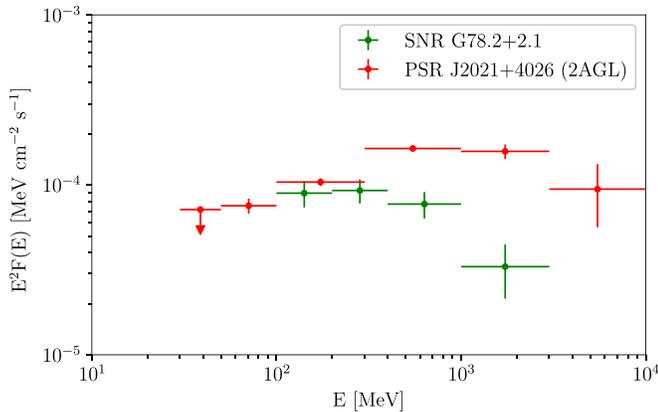

Figure 7. Spectrum of the SNR G78.2+2.1 as detected with the off-pulse analysis by *AGILE* (green), compared with the spectrum of the pulsar PSR J2021+4026 from the second *AGILE* catalog (red, 2AGL J2021+4029, Bulgarelli et al. 2019).

account the *AGILE* PSF above 400 MeV, we considered in our extended analysis the average off-pulse emission detected by the *AGILE*-GRID from the whole SNR angular extent.

4. Multiwavelength Spectrum and Modeling

For the analysis of the SNR spectral energy distribution (SED), we considered the *AGILE*-GRID spectral data together with data from the literature, referred to the whole extent of the SNR shell. In our models we took into account only the nonthermal contributions to the overall multiwavelength SED.

Together with the *AGILE* data, we considered radio data (from Higgs 1977; Higgs et al. 1977; Pineault & Chastenay 1990; Wendker et al. 1991; Zhang et al. 1997; Kothes et al. 2006; Gao et al. 2011) and *Fermi*-LAT data (from Ackermann et al. 2017 and Abeysekara et al. 2018). The γ -ray data from *Fermi*-LAT are related to an energy band for which the emission of the pulsar is naturally turned off (cutoff energy $E_{\text{cut-off}} \simeq 2.4$ GeV). Thus, the high-energy γ -ray emission can be assumed to belong to the SNR.

An X-ray analysis of the region was presented by Hui et al. (2015), showing *Chandra* and *XMM-Newton* data possibly related to the SNR emission. Since no evidence of nonthermal radiation was found by the authors, we did not account for their spectra in our nonthermal modeling.

During the last few years, several works on the γ -ray emission from this SNR (Lande et al. 2012; Aliu et al. 2013; Fraija & Araya 2016; Ackermann et al. 2017; Abeysekara et al. 2018) have been published, but because of the presence of the pulsar all the analyses were focused on energies above 1 GeV, where its contribution becomes subdominant. In this paper, the off-pulsed analysis of the γ -ray emission from the region allowed us to extract the SNR contribution down to hundreds of MeV energies. In this section, we try to model the data with both hadronic and leptonic populations, following the reacceleration/acceleration model described in Cardillo et al. (2016) and tuning several parameters of the systems according to what we expect in this kind of environment.

For the likelihood analyses of the off-pulsed extended emission, we used the whole radio emitting region as a template. Consequently, to obtain the simplest model possible, we assumed that the γ -ray emission detected by *AGILE* (this paper) and *Fermi*-LAT (Ackermann et al. 2017; Abeysekara et al. 2018) can be explained by an overall model, based on the same parameters.

As is largely explained in Cardillo et al. (2016), we have a lot of parameters to consider. To reduce the degrees of freedom, we have taken some parameters to be fixed as found in the literature: the distance, $d = 1.5$ kpc, and the age, $t_{\text{age}} = 6.5 \times 10^3$ yr (Fraija & Araya 2016); the SNR dimension, $D = 64'$ (Higgs 1977). We also limited the shock velocity values to a range that takes into account recent estimations over

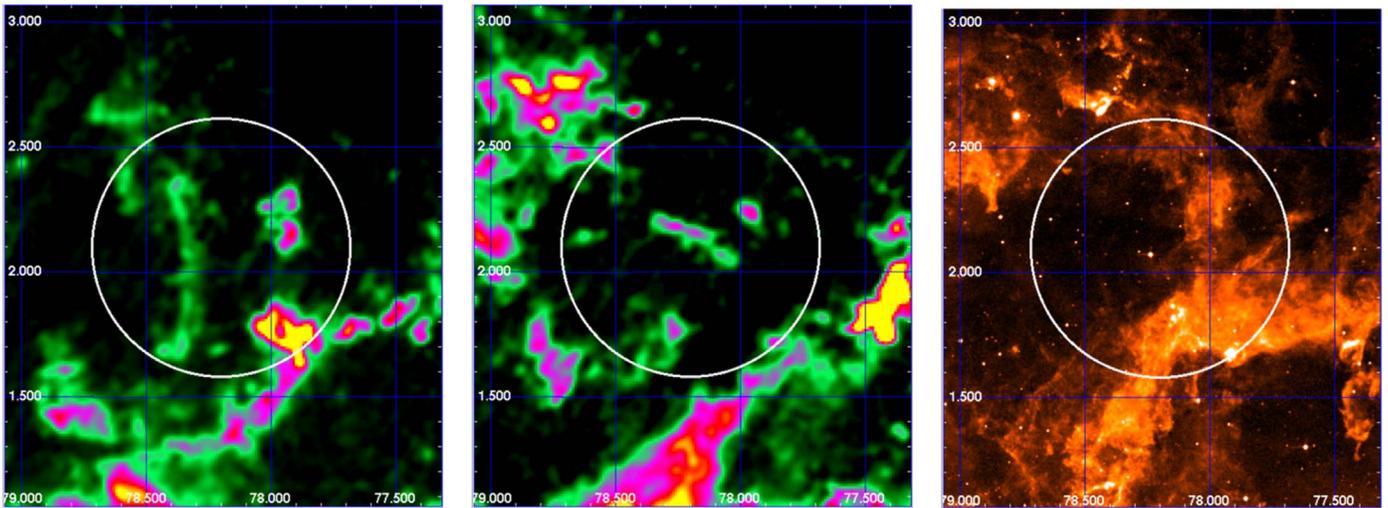

Figure 8. Left panel: ^{13}CO ($J = 1 \rightarrow 0$) line integrated emission between -20 and 0 km s^{-1} from FCRAO survey in Galactic coordinates. Central panel: ^{13}CO ($J = 1 \rightarrow 0$) line integrated emission between 0 and 20 km s^{-1} from FCRAO survey in Galactic coordinates. Right panel: *MSX* (band *A*) infrared image at $8.23 \mu\text{m}$ (pixel size = $6''$) in Galactic coordinates. The white circle indicates the radio shell extent of the Gamma Cygni SNR.

the last years, $750 \div 1500 \text{ km s}^{-1}$ (Fraija & Araya 2016 and references therein).

All the parameters used in our modeling are physically reasonable and tuned to get the best emission model for our source (see Cardillo et al. 2016, for a description of all the dependencies of these parameters): the interaction time (between the shock and the surrounding medium) t_{int} , the shock velocity v_{sh} , the initial magnetic field B_0 , the magnetic field of the compressed downstream medium B_m , the initial density n_0 , the compressed downstream density n_m , the momentum spectral index α depending on the compression ratio r ($\alpha = \frac{3r}{r-1}$), the maximum energy of accelerated particles E_{max} , the filling factor f_V defined in the source volume $V = f_V \frac{4}{3} \pi R^3$, the magnetic perturbation correlation length L_c , and the acceleration efficiency ξ_{CR} .

The leptonic processes that we took into account are: synchrotron, Bremsstrahlung, and inverse Compton (IC) processes (both on cosmic microwave background, CMB, and interstellar radiation, ISR). The hadronic emission model estimates the γ -ray emission from the decays of the π^0 mesons ($\pi^0 \rightarrow \gamma\gamma$) produced in proton–proton inelastic scatterings, and from secondary electrons produced in charged pion decays.

In our modeling of the SNR SED, we considered two main scenarios. In the first one, we take into account the emission from the whole SNR angular extent: in the γ -ray band we consider the *AGILE* spectrum together with the *Fermi*-LAT data from Ackermann et al. (2017) and Abeysekara et al. (2018), both calculated over the $\sim 1^\circ$ extent of the SNR. We present both single population and double-population emission models. In the second scenario, we focus on the NW rim of the shell, at the position of the VER J2019+407 source: in the γ -ray band we consider the *Fermi*-LAT spectrum from Fraija & Araya (2016) and Abeysekara et al. (2018), and the VERITAS spectrum from Aliu et al. (2013) and Abeysekara et al. (2018).

4.1. The Overall Model

We know that in our Galaxy there is a sea of Galactic cosmic rays (CRs) that could be reaccelerated by a first-order Fermi mechanism in correspondence of the SNR shocks (Cardillo et al. 2016, and references therein). Consequently, we tried to

compute radio and γ -ray emission due to reacceleration of preexisting CRs. However, the initial density value is too low to provide a reacceleration contribution sufficiently high to explain the *AGILE* γ -ray detection.

Thus, we neglected reacceleration and we focused our analysis on possible freshly accelerated particles, analyzing both hadronic and leptonic dominant emission.

As described above, the data set refers to the whole SNR extent. In the SED modeling, we also plotted the ASCA and VERITAS data in gray as reference (and upper limit) values, even if they are related to the NW rim of the shell.

4.1.1. Hadrons

In Figure 9 we show both radio (left) and γ -ray (right) SED with our best hadronic acceleration emission model obtained with $t_{\text{int}} = 0.9 \times t_{\text{age}}$, $v_{sh} = 850 \text{ km s}^{-1}$, $L_c = 0.2 \text{ pc}$, $B_0 = 8.5 \mu\text{G}$, $B_m = 21.9 \mu\text{G}$, $n_0 = 10 \text{ cm}^{-3}$, and $n_m = 31.4 \text{ cm}^{-3}$. We used a simple power-law distribution for both nuclei and electrons, with a momentum index $\alpha = 4.4$. The derived cut-off particle energy is at $E_{\text{max}} = 5.9 \text{ TeV/n}$ ($\sim 590 \text{ GeV}$ for γ -ray). With low CR acceleration efficiency $\xi_{\text{CR}} = 0.2\%$, the γ -ray emission from π^0 decay can explain both *AGILE* and *Fermi*-LAT (Ackermann et al. 2017; Abeysekara et al. 2018) data points. The Bremsstrahlung contribution becomes dominant at $E < 10 \text{ MeV}$ and IC emission is completely negligible because of the high density value.

However, this model cannot in any way explain the detected radio emission, even because only primary electrons contribute to radio spectrum, because the density value is not sufficient to give a higher secondary electron production from π^\pm -decays. The expected Bremsstrahlung emission slightly exceeds the ASCA data. Furthermore, the modeling of the γ -ray spectrum is not accurate based exclusively on this simple hadronic scenario.

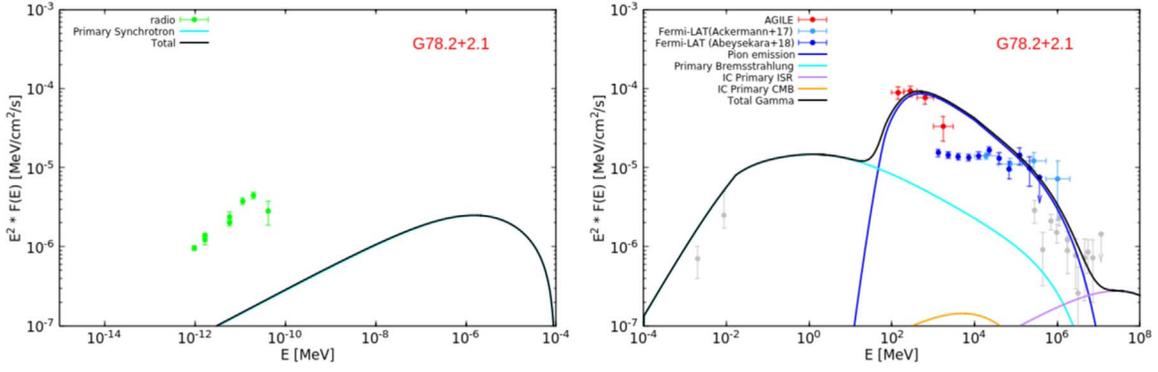

Figure 9. Single population hadronic model. Left panel: radio spectrum, average emission from the whole extent of the SNR G78.2+2.1 (Higgs 1977; Higgs et al. 1977; Pineault & Chastenay 1990; Wendker et al. 1991; Zhang et al. 1997; Kothes et al. 2006; Gao et al. 2011) with the corresponding leptonic component of a hadron-dominated emission model. Right panel: *AGILE*-GRID (100 MeV–3 GeV) and *Fermi*-LAT (1–500 GeV from Abeysekara et al. 2018, 0.01–2.00 TeV from Ackermann et al. 2017) spectra, average emission from the whole extent of the SNR with the corresponding hadron-dominated emission model. Gray data points in the background are related to the emission from the region of VER J2019+407 only.

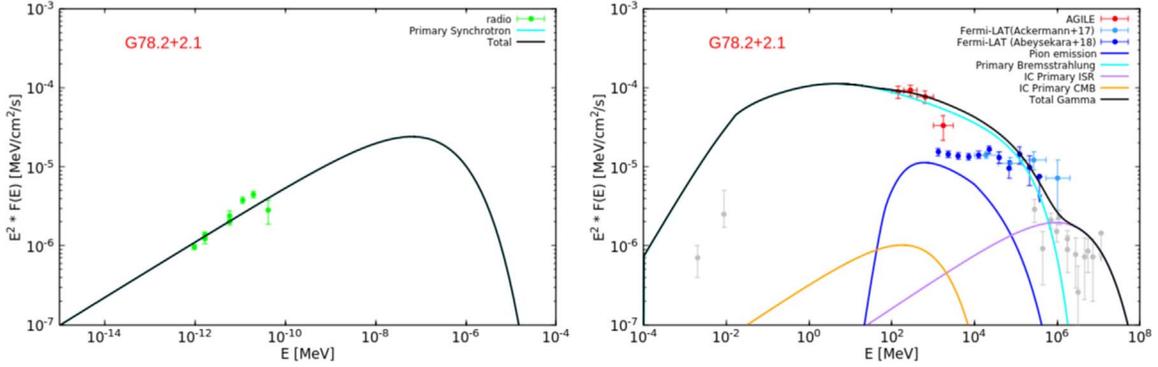

Figure 10. Single population leptonic model. Left panel: radio spectrum, average emission from the whole extent of the SNR G78.2+2.1 (same as in Figure 9) with the corresponding leptonic component of a lepton-dominated emission model. Right panel: *AGILE*-GRID and *Fermi*-LAT spectra (the same as in Figure 9) with the corresponding lepton-dominated emission model.

4.1.2. Leptons

4.1.2.1. Single Population

In order to fit both γ -ray and radio emission, we consider a leptonic emission model, shown in Figure 10, with an electron/proton ratio equal to 1.

This model was obtained with parameters slightly different from the hadronic one, but always consistent with the physics of the system; $t_{\text{int}} = 0.8 \times t_{\text{age}}$, $v_{sh} = 850 \text{ km s}^{-1}$, $L_c = 0.8 \text{ pc}$, $B_0 = 9.5 \mu\text{G}$, $B_m = 25.6 \mu\text{G}$, $n_0 = 10 \text{ cm}^{-3}$, and $n_m = 33.1 \text{ cm}^{-3}$. The simple power-law distribution has a harder momentum index, $\alpha = 4.3$, implying also a lower efficiency value, $\xi_{\text{CR}} = 0.02\%$. The derived particle maximum energy is $E_{\text{max}} = 5.2 \text{ TeV}/n$ ($\sim 520 \text{ GeV}$ for γ rays).

As shown in Figure 10, the leptonic model can explain both radio and γ -ray emission, even though the GeV domain is not accurately fitted. We note that the γ -ray emission is dominated by the Bremsstrahlung emission, strongly related to the density value, and the IC contribution is higher (than the hadronic scenario) because of the higher electron/proton ratio. However, the expected emission in the X-ray band is much higher than the ASCA data, indicating that this model is not accurate to describe the high-energy nonthermal radiation from the SNR.

4.1.2.2. Double Population

We found that both hadronic and leptonic models with a single population cannot accurately explain the radio, X-ray, and γ -ray emission from G78.2+2.1. Thus we considered the possibility that the MeV–GeV γ -ray emission detected by *AGILE* is due to a population interacting with a higher density medium, and the GeV–TeV emission detected by *Fermi*-LAT (Ackermann et al. 2017; Abeysekara et al. 2018) to a population interacting with a lower density medium.

Since we do not have any information about the extent of higher and lower density regions of the remnant, we use the simplest approach and consider equal filling factors, $f = 50\%$ of the volume.

We consider only the leptonic model for both populations, because there is no way to properly fit the radio emission with a double-population hadronic model.

In Figure 11, our best double-population model is shown. We note how the first population (high density) can explain the *AGILE* and radio data sets; from Figure 5, it is evident that the most prominent radio peak is strongly correlated with the *AGILE* γ -ray detected emission. On the other hand, the second population (low density) properly fits the *Fermi*-LAT emission above 1 GeV and the X-ray emission detected by ASCA (Uchiyama et al. 2002).

For the first population, we assumed $t_{\text{int}} = 0.3 \times t_{\text{age}}$, $n_0 = 50 \text{ cm}^{-3}$, $v_{sh} = 750 \text{ km s}^{-1}$, $L_c = 2.9 \text{ pc}$, $B_0 = 21 \mu\text{G}$,

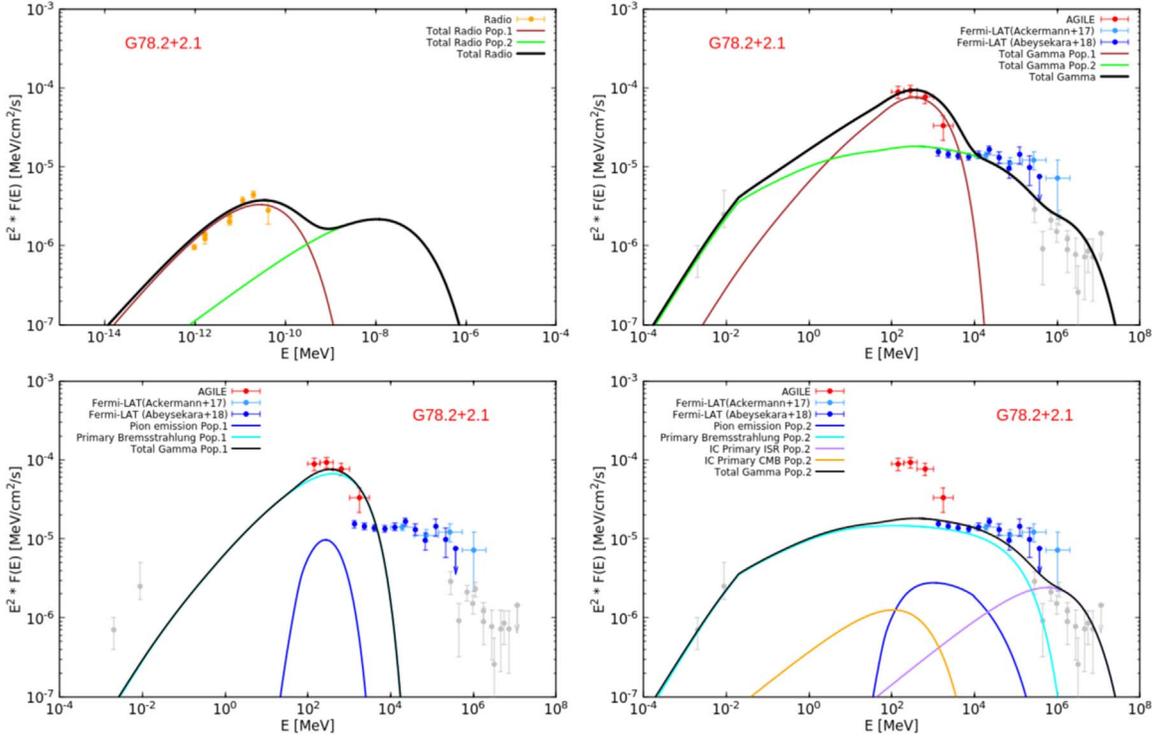

Figure 11. Top panels: double-population leptonic model. Top left panel: radio spectrum, total emission in black from the two leptonic populations, Pop. 1 (brown) and Pop. 2 (green). Top right panel: *AGILE*-GRID (100 MeV–3 GeV), *Fermi*-LAT (whole SNR, 1–500 GeV from Abeysekara et al. 2018, 0.01–2.00 TeV from Ackermann et al. 2017), with the corresponding total γ -ray emission from two leptonic populations, Pop. 1 (brown) and Pop. 2 (green). Bottom panels: high-energy emission model components in detail for the two populations. Bottom left panel: first population. Bottom right panel: second population.

$\alpha = 3.6$ and $\xi_{\text{CR}} = 1.4 \times 10^{-5}$, obtaining $B_m = 104 \mu\text{G}$, $n_m = 300 \text{ cm}^{-3}$, $E_{\text{max}} = 2 \text{ GeV/n}$.

For the second population, we assumed $t_{\text{int}} = t_{\text{age}}$, $n_0 = 2.5 \text{ cm}^{-3}$, $v_{sh} = 920 \text{ km s}^{-1}$, $L_c = 1.0 \text{ pc}$, $B_0 = 2.4 \mu\text{G}$, $\alpha = 4.2$, and $\xi_{\text{CR}} = 1.1 \times 10^{-1}$, obtaining $B_m = 7 \mu\text{G}$, $n_m = 9 \text{ cm}^{-3}$ and $E_{\text{max}} = 363 \text{ GeV/n}$.

4.2. Modeling the VER J2019+407 Source

For completeness, we also studied a model for the region associated with the VERITAS source VER J2019+407 (Aliu et al. 2013) in the NW rim of the SNR, considering also the corresponding *Fermi*-LAT spectrum (Fraija & Araya 2016; Abeysekara et al. 2018). For this model, we also took into account the X-ray spectra detected by ASCA (Uchiyama et al. 2002) in the NW region (hard clumps), which are characterized by a nonthermal power-law tail and positionally consistent with the VERITAS source. The radio emission in the region of the GeV–TeV source (Higgs 1977) was also considered in this model.

In order to model the emission of the GeV–TeV source VER J2019+407, we fixed a lower initial density value at $n_0 = 0.5 \text{ cm}^{-3}$ ($n_m = 1.7 \text{ cm}^{-3}$), lower than the one used in the work of Fraija & Araya (2016) but similar to the one used in Aliu et al. (2013). Our assumption is that the remnant is interacting with this lower density region for a longer time, $t_{\text{int}} = t_{\text{age}}$, and with a higher velocity, $v_{sh} = 1200 \text{ km s}^{-1}$ consistently with a propagation in a lower density medium. Magnetic field is lower, $B_0 = 2.1 \mu\text{G}$ ($B_m = 5.7 \mu\text{G}$), and the correlation length is higher, $L_c = 1.9 \text{ pc}$. We used a small filling factor, $f_V = 20\%$, based on the angular extent of the observed GeV–TeV source. The maximum energy is $E_M = 6.5 \text{ TeV/n}$, the momentum index is $\alpha = 4.3$, and the

acceleration efficiency is $\xi_{\text{CR}} = 1.0\%$. In this case, due to the lower density and the lower magnetic field value, the IC on the ISR is dominant at higher energies and fits the γ -ray data points detected by *Fermi*-LAT and VERITAS (see Figure 12, right panel).

The Bremsstrahlung contribution is dominant at GeV and X-ray energies, well fitting the ASCA data points. Moreover, the provided radio synchrotron emission explains the radio flux within the VERITAS source (Fraija & Araya 2016, and references within).

5. Discussion

Our analysis was carried out considering the whole SNR to be an emitter, by analyzing the data detected at radio wavelengths and γ -ray frequencies by *AGILE* and *Fermi*-LAT (Ackermann et al. 2017; Abeysekara et al. 2018). The parameters used, consistent with the literature and derived according to the equations in Cardillo et al. (2016), provide a negligible contribution from preexisting reaccelerated CRs. Consequently, we considered hadronic and leptonic acceleration as the only contribution to γ -ray and radio emission from the SNR G78.2+2.1.

We found that a single population emission model cannot properly account for the radio, X-ray and γ -ray nonthermal emission, whereas a double-population leptonic model fits the data in a satisfactory way (see Figure 11). The population of accelerated leptons interacting with a high density medium can account for the MeV–GeV emission detected by *AGILE* (bottom left panel of Figure 11), and is related to dominant Bremsstrahlung processes. On the other hand, the second population, interacting with a lower density medium, is able to account for the GeV–TeV emission detected by *Fermi*-LAT

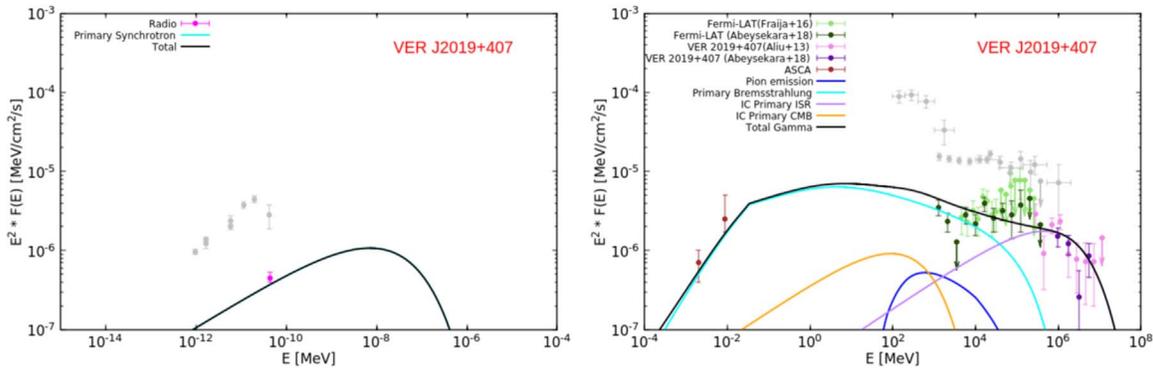

Figure 12. Leptonic model for the γ -ray emission detected in the northwestern side of the SNR (VER J2019+407, see Figure 4). Left panel: radio emission from the GeV–TeV region (Higgs 1977) with the corresponding leptonic component of a lepton-dominated emission spectrum. Right panel: ASCA (2–10 keV, hard X-ray clumps, Uchiyama et al. 2002, *Fermi*-LAT (1–500 GeV from Abeysekara et al. 2018, 4–300 GeV from Fraija & Araya 2016) and VERITAS (Aliu et al. 2013; Abeysekara et al. 2018) data with the corresponding lepton-dominated emission model. Gray data points in the background are related to the emission from the whole region of the SNR G78.2+2.1.

(Ackermann et al. 2017; Abeysekara et al. 2018). In this case, Bremsstrahlung processes (in a lower density medium) are dominant below ~ 250 GeV, and IC processes represent the main emission mechanism at the highest energies. We remark that, even though both the *AGILE* and *Fermi*-LAT spectra are referred to the whole SNR angular extent, the first population is possibly associated with the activity of the SE rim of the shell, where most of the *AGILE* emission is detected; on the other hand, the second population is most likely associated with the NW rim, where most of the *Fermi*-LAT emission is observed (see Figure 13). Interestingly, CO and IR emission maps (see Figure 8) indicate a concentration of dense gas in the SE rim of the shell, supporting our hypothesis of a high density medium in coincidence with the emission detected by *AGILE*.

The resulting scenario is a nonsymmetrical shell where two populations of accelerated particles interact with different environments located in two regions coincident with two bright radio features: one is related with the MeV–GeV domain (SE), the other with the GeV–TeV emission (NW). According to the analysis carried out by Ladouceur & Pineault (2008), the SE and NW regions represent the brightest nonthermal region of the shell, indicating sites of intense synchrotron emission from shock-accelerated electrons propagating in a highly inhomogeneous medium.

We also presented the results from a further theoretical model that can account for the local emission of the *Fermi*-LAT/VERITAS γ -ray source VER J2019+407. Even in this case, the reacceleration is totally negligible. According to our study, a simple leptonic model is able to fit the data in the radio, X-ray, and γ -ray bands, by assuming a low initial density $n_0 = 0.5 \text{ cm}^{-3}$ and a higher shock velocity $v_{sh} = 1200 \text{ km s}^{-1}$. Our theoretical expectations for the emission model in this region are fully consistent with the X-ray “hard clump” reported by Uchiyama et al. (2002) in the NW rim of the shell: nonthermal Bremsstrahlung in a lower density medium (with respect to the SE rim) is consistent with the hard power-law tail detected by ASCA at 2–10 keV. As in Fraija & Araya (2016), our model requires a lower density medium with respect to the 10 cm^{-3} adopted by Uchiyama et al. (2002), which would overpredict the GeV–TeV emission in this region. Nevertheless, in order to properly fit the data, we assumed a higher shock velocity with respect to the one derived by the authors of that paper.

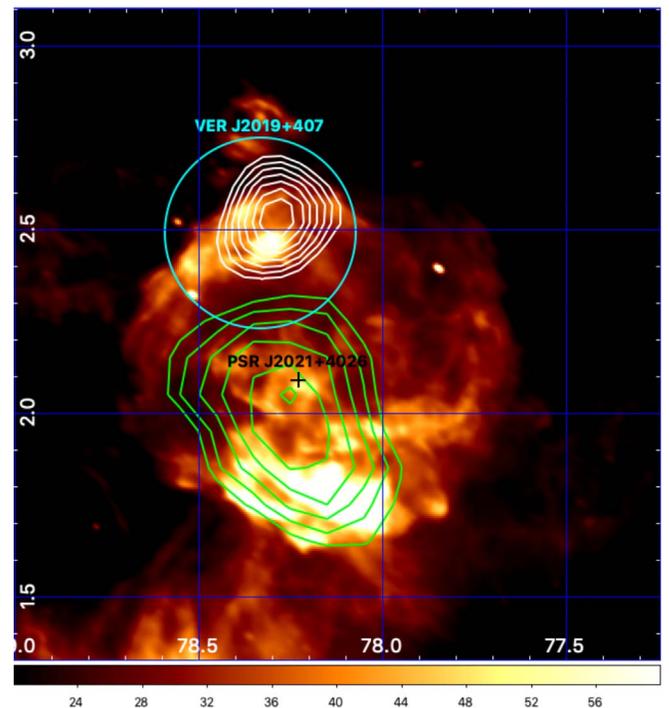

Figure 13. Radio image of the SNR G78.2+2.1 at 21.1 cm wavelength (frequency = 1420 MHz, bandwidth = 30 MHz), pixel size = $20''$, DRAO Radio Telescope. Green contours: *AGILE*-GRID contour levels, related to the off-pulse intensity map above 400 MeV. White contours: *Fermi*-LAT contour levels related to the background subtracted *TS* map (photon energies greater than 10 GeV, $TS > 36$ with 3-pixel Gaussian smoothing), from Ackermann et al. (2017). The cyan circle marks the position of the extended TeV source, VER J2019+407, as detected by VERITAS (Aliu et al. 2013). The black cross marks the position of the pulsar PSR J2021+4026.

6. Conclusions

In this paper we analyzed the γ -ray emission in the direction of the SNR G78.2+2.1, by selecting only the off-pulsed interval of the pulsar PSR J2021+4026. As a consequence of this approach, we are able to unveil, for the first time, the γ -ray emission from the SNR at energies lower than 1 GeV. We showed that, if the emission underlying the intense γ -ray radiation from the pulsar is taken into account with an off-pulse analysis, a complex pattern of γ -ray emission emerges, showing the SNR-accelerated particles interacting with the

surrounding gas clouds and ISR photons. We found that the *AGILE*-GRID off-pulsed emission profile above 400 MeV appears to partially cover the SE rim of the shell. On the other hand, most of the GeV–TeV emission (*Fermi*-LAT/*VERITAS*) is located on the NW side.

The γ -ray SED detected by *AGILE* from the whole SNR angular extent is presented.

A lepton-dominated double-population model can explain both the radio and the high-energy γ -ray emission from the whole extent of the SNR, indicating that the MeV–GeV emission is related to Bremsstrahlung processes in a high density medium, whereas the GeV–TeV radiation is due to both nonthermal Bremsstrahlung ($E_\gamma \lesssim 250$ GeV) and IC processes ($E_\gamma \gtrsim 250$ GeV) in a lower density medium. Observations strongly suggest that the first population of leptons is associated with the SE part of the shell (in coincidence with the bright radio feature DR4 and a higher gas density), and the second population with the NW rim.

The *AGILE* observations are contributing in a crucial way to elucidate the low-energy domain of the spectrally resolved γ -ray morphology of G78.2+2.1.

Future observations at radio wavelengths with the Square Kilometre Array (SKA) and at TeV energies with the Cerenkov Telescope Array (CTA) will shed new light on the understanding of the physics behind the nonthermal emission from this SNR.
