Abstract

Asteroseismology of solar-like oscillators often relies on the comparisons between stellar models and stellar observations in order to determine the properties of stars. The values of the global seismic parameters, ν_{\max} (the frequency where the smoothed amplitude of the oscillations peak) and $\Delta\nu$ (the large frequency separation), are frequently used in grid-based modeling searches. However, the methods by which $\Delta\nu$ is calculated from observed data and how $\Delta\nu$ is calculated from stellar models are not the same. Typically for observed stars, especially for those with low signal-to-noise data, $\Delta\nu$ is calculated by taking the power spectrum of a power spectrum, or with autocorrelation techniques. However, for stellar models, the actual individual mode frequencies are calculated and the average spacing between them directly determined. In this work we try to determine the best way to combine model frequencies in order to obtain $\Delta\nu$ that can be compared with observations. For this we use stars with high signal-to-noise observations from *Kepler* as well as simulated *Transiting Exoplanet Survey Satellite* data of Ball et al. We find that when determining $\Delta\nu$ from individual mode frequencies the best method is to use the $\ell = 0$ modes with either no weighting or with a Gaussian weighting around ν_{\max} .

Key words: stars: fundamental parameters – stars: interiors – stars: oscillations

1. Introduction

In the field of asteroseismology, stellar models play a key role in determining the properties of observed stars. Just by knowing the basic seismic parameters, ν_{\max} (the frequency where the smoothed amplitude of the oscillations peak) and $\Delta\nu$ (the large frequency separation), as well as T_{eff} for a star, models can be used to place constraints on stellar age, radius, and mass. Since there is such frequent reliance on matching the seismic parameters determined from observations to the seismic parameters extracted from stellar models, we need to be sure that the methods by which we calculate $\Delta\nu$ and ν_{\max} from models produce accurate representations of the observed global values. Determining the correct way to extract the value of $\Delta\nu$ and ν_{\max} from a stellar model is therefore of great importance.

The large frequency separation, $\Delta\nu$, is the average frequency spacing between modes of adjacent radial order (n), of a given degree (ℓ). The radial order n is the number of nodes in the radial direction and ℓ is the number of node lines on the star's surface. This quantity $\Delta\nu$ arises from the asymptotic relation (Tassoul 1980; Gough 1986), which is applicable for modes of low ℓ and high n . The relation is not exact and the spacings between the modes have some variability. Therefore, the value of $\Delta\nu$ will depend on the method by which this average spacing is calculated.

The value of $\Delta\nu$ can be approximately related to the density of the star, as $\Delta\nu \propto \sqrt{\bar{\rho}}$ (see, e.g., Tassoul 1980; Ulrich 1986; Christensen-Dalsgaard 1988, 1993). This leads to the $\Delta\nu$ scaling relation

$$\frac{\Delta\nu}{\Delta\nu_{\odot}} \simeq \sqrt{\frac{M/M_{\odot}}{(R/R_{\odot})^3}}. \quad (1)$$

For an observed star, the value of $\Delta\nu$ can be determined from the excited p-modes in the star's power spectrum. This

observed $\Delta\nu$ is not usually calculated directly from individual mode spacings, as this would require high signal-to-noise, but instead through other methods. For example, $\Delta\nu$ is often determined by taking a power spectrum of a power spectrum (Hekker et al. 2010; Mathur et al. 2010) or autocorrelation techniques (Roxburgh & Vorontsov 2006; Huber et al. 2009; Mosser & Appourchaux 2009; Roxburgh 2009; Verner & Roxburgh 2011; Kiefer 2013).

It is important to note that this is not how the value of $\Delta\nu$ is determined for stellar models. Since for a stellar model the radius and mass are known quantities, a simple approach to determine $\Delta\nu$ would be to make use of the $\Delta\nu$ scaling relation in Equation (1). However, studies have shown that the $\Delta\nu$ scaling relation has deviations, is a function of T_{eff} and $[\text{Fe}/\text{H}]$, and only holds to a few percent (White et al. 2011; Miglio et al. 2013; Mosser et al. 2013; Guggenberger et al. 2016; Sharma et al. 2016; Yıldız et al. 2016; Rodrigues et al. 2017; Ong & Basu 2019). Therefore, $\Delta\nu$ for stellar models is not usually determined using the scaling relation, but by calculating the model's individual mode frequencies. The value of $\Delta\nu$ can then be calculated by finding the average spacing between these frequencies (of a certain ℓ). This average is usually determined as the slope of a linear fit to the ν - n relationship for modes of a given ℓ . Since the spacing of modes is not exactly the same throughout the excited mode envelope, then the manner in which the averaging is performed is important. This leaves some ambiguity as to what the best method of calculating $\Delta\nu$ from these individual mode frequencies is. For example, which ℓ modes to include in the averaging or whether to weight the modes around ν_{\max} more heavily, are decisions that can produce important differences in the value of $\Delta\nu$. Rodrigues et al. (2017) show that there is a difference between Gaussian-weighted and error-weighted values of $\Delta\nu$.

up to about 1%. Roxburgh (2014) also discusses that depending on the method of calculating $\Delta\nu$, the results can differ by about 1%. If relying on the scaling relation to determine mass, a 1% deviation in $\Delta\nu$ can have a meaningful impact.

The frequency where the smoothed amplitude of the oscillations peak, ν_{\max} , can be shown to be proportional to the acoustic cutoff frequency, ν_{ac} (Belkacem et al. 2011), and goes as $\nu_{\max} \propto \nu_{\text{ac}} \propto gT_{\text{eff}}^{-1/2}$ (Brown et al. 1991; Kjeldsen & Bedding 1995; Bedding & Kjeldsen 2003; Belkacem et al. 2011). This leads to the ν_{\max} scaling relation, given by

$$\frac{\nu_{\max}}{\nu_{\max,\odot}} \simeq \left(\frac{M}{M_{\odot}}\right) \left(\frac{R}{R_{\odot}}\right)^{-2} \left(\frac{T_{\text{eff}}}{T_{\text{eff},\odot}}\right)^{-1/2}. \quad (2)$$

While one could determine the approximate value of ν_{\max} for a stellar model using Equation (2), the ν_{\max} scaling relation must be used with caution, as many studies have shown that deviations do exist (Bedding & Kjeldsen 2003; Stello et al. 2009; Bruntt et al. 2010; Miglio 2012; Bedding 2014; Coelho et al. 2015; Silva Aguirre et al. 2015; Yildiz et al. 2016; Viani et al. 2017). For stellar models, a more accurate way to calculate ν_{\max} is to avoid the ν_{\max} scaling relation and instead use the acoustic cutoff frequency, as described in Viani et al. (2017).

In this paper we investigate various methods of calculating the large frequency separation from individual mode frequencies (referred to as $\Delta\nu_{\text{freq}}$ from now on) to determine which method gives values of $\Delta\nu$ that best represent the global observational $\Delta\nu$ values. This will be done using observations of high signal-to-noise stars, with individual mode frequencies already determined from previous studies in the literature. For these stars, the individual mode frequencies will serve as a proxy for the frequency values that one would have if they were modeling the star. For each star in our sample, the value of $\Delta\nu_{\text{freq}}$ will be calculated using a variety of methods and compared to the global value of $\Delta\nu$, calculated using standard observational methods. This will allow us to determine the optimal way to calculate $\Delta\nu$ from individual mode frequencies and develop a better understanding of how $\Delta\nu_{\text{freq}}$ of stellar models should be determined. We then verify these results using the Ball et al. (2018) simulations of light curves for NASA’s *Transiting Exoplanet Survey Satellite* (*TESS*; Ricker et al. 2015). This issue is especially important as a multitude of new observations from *TESS* become available.

The paper is organized as follows. Section 2 gives an overview on the stars used in the study, explains the methods used to determine the seismic parameters from the observed data, and discusses the various methods used to calculate $\Delta\nu$ from the individual mode frequencies. Section 3 presents the results and compares the different values of $\Delta\nu$. Section 4 discusses the findings, and Section 5 provides concluding remarks.

2. Data and Analysis

2.1. Sample of Stars in the Study

The stars used in this study consist of the 66 main-sequence stars from the *Kepler* Asteroseismic LEGACY Sample from Lund et al. (2017), 34 solar-type planet-hosting stars from Davies et al. (2016), the 23 main-sequence and subgiant stars from Appourchaux et al. (2012) that were not already included from the LEGACY Sample, and 17 red giant stars from NGC

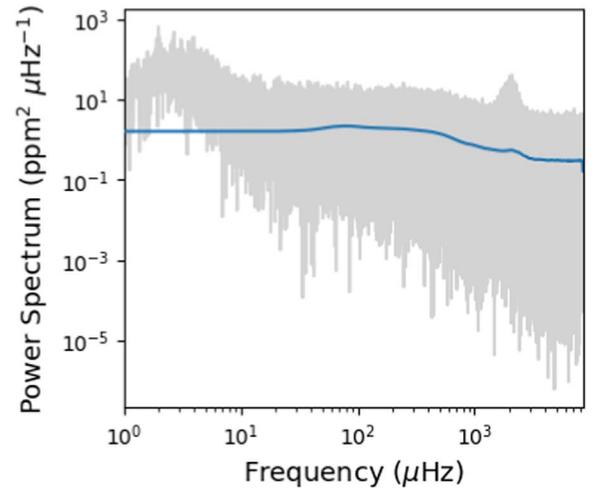

Figure 1. Power spectrum for KIC 6116048. The blue line shows the smoothed background estimate.

6791 that were in Corsaro et al. (2017a) and McKeever et al. (2019). It should be noted that while Davies et al. (2016) examined 35 stars, we excluded KIC 8684730 as it did not have a readily available multi-quarter power spectrum. For each of the 140 stars in our sample, the *Kepler* power spectrum was obtained from the KASOC website.⁵ For the main-sequence and subgiant stars the short-cadence KASOC weighted version of the power spectra were used while for the RGB stars the “Working Group 8” long-cadence data were used. The seismic parameters were extracted from the power spectrum using several different methods as described in Section 2.2.

2.2. Determining Seismic Parameters from Power Spectra

2.2.1. 2D Autocorrelation Method

One method to determine the value of ν_{\max} and $\Delta\nu$ from a power spectrum is the 2D autocorrelation function (ACF) method, as in Huber et al. (2009), Verner & Roxburgh (2011), and Kiefer (2013). The premise of this technique is to perform a series of autocorrelations on segments of the power spectrum to determine the frequency range of the envelope of excited modes. First the power spectrum is smoothed, to estimate the background, using a median filter with a window size of 100 μHz for the main-sequence and subgiant stars and a window of 10 μHz for the giants. An example of this smoothing for star KIC 6116048 can be seen in Figure 1. Then the power relative to the smoothed background spectrum (PBS) is determined using Equation (3) (Verner & Roxburgh 2011; Kiefer 2013):

$$\text{PBS}(\nu) = \frac{P(\nu) - \text{Bg}(\nu)}{\text{Bg}(\nu)}, \quad (3)$$

where $P(\nu)$ is the power at a given frequency and $\text{Bg}(\nu)$ is the smoothed background.

A series of autocorrelations are then performed on different segments of the PBS. Starting with the lowest frequency in the power spectrum, an autocorrelation is calculated for a 250 μHz wide window (25 μHz window for the giant stars). The window size for the main-sequence stars was chosen to match that of Kiefer (2013). The central frequency of the window is then

⁵ kasoc.phys.au.dk

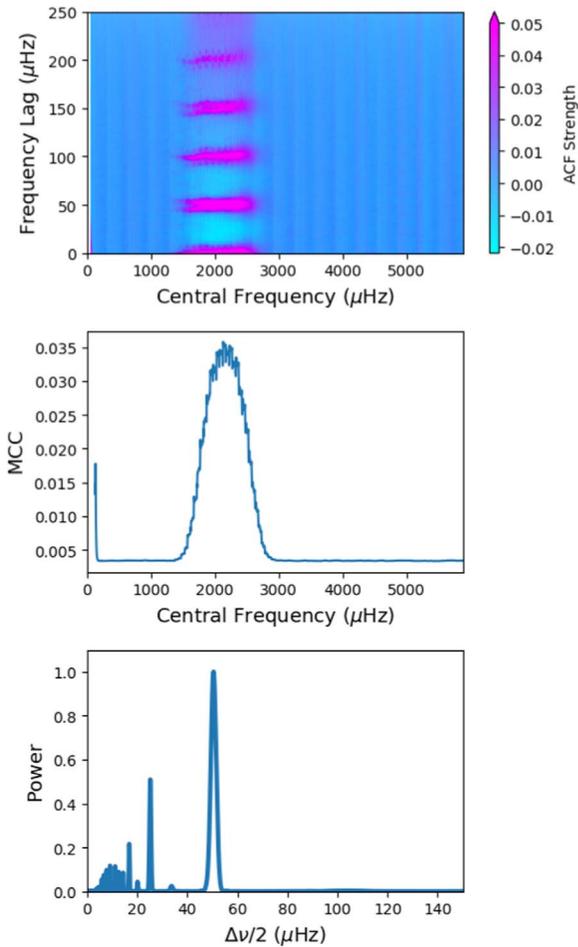

Figure 2. Top: the 2D autocorrelation results for KIC 6116048. The abscissa shows the central window frequency, the ordinate shows the autocorrelation lag, and the colors indicate the autocorrelation power. Middle: the mean collapsed correlation (MCC). The abscissa shows the central window frequency and the ordinate shows the average absolute value of the autocorrelation power for each window (see Equation (4)). Bottom: the power as a function of $\Delta\nu/2$ for the $\text{PS}\otimes\text{PS}$ of the p-mode envelope for the example star KIC 6116048.

shifted by $1\ \mu\text{Hz}$ (as in Verner & Roxburgh 2011 and Kiefer 2013), toward higher frequencies, and another autocorrelation is performed. This is continued until the window reaches the end of the power spectrum. The results of this process can be seen in the top panel of Figure 2, where the autocorrelation power for each frequency lag can be plotted as a function of the central window frequency.

As can be seen in the top panel of Figure 2, when in the frequency range of the excited p-modes, the autocorrelation power spikes with a regular spacing that corresponds to $\Delta\nu/2$. This clear pattern in the autocorrelation power is not present outside of the frequency range of the p-mode envelope. Thus, by examining where the autocorrelation shows this spacing, we can determine the frequency range of the envelope of excited modes as well as the value of ν_{max} .

To make this more clear, we can collapse the top panel in Figure 2 to examine just the total average autocorrelation power at each central frequency. This quantity, called the mean collapsed correlation (MCC; Kiefer 2013), is calculated for

each central frequency as

$$\text{MCC} = \frac{\left(\sum_{i=1}^{n_{\text{lags}}} |\text{ACF}_i|\right) - 1}{n_{\text{lags}}}, \quad (4)$$

where n_{lags} is the number of lags in the ACF. In the numerator 1 is subtracted because at lag 0 the autocorrelation is 1 since the spectrum has not been shifted. The presence of the absolute value in the equation is because a negative correlation power also holds valuable information. We plot the MCC as a function of central window frequency in the middle panel of Figure 2, again for KIC 6116048.

From the collapsed 2D autocorrelation, the frequency range in which the excited p-modes reside can clearly be seen. A Gaussian is then fit to the MCC peak, with the Gaussian's center being ν_{max} , as done for example by Huber et al. (2009), Verner & Roxburgh (2011), and Kiefer (2013). The envelope of excited p-modes is then defined, following Kiefer (2013), to be the frequency range around ν_{max} where the MCC value is at least 10% of the Gaussian peak height.

Once the frequency range of the excited p-mode envelope is determined, the value of $\Delta\nu$ can be calculated by taking a power spectrum of the power spectrum ($\text{PS}\otimes\text{PS}$) for this frequency range (see, e.g., Hekker et al. 2010; Mathur et al. 2010). A Lomb–Scargle periodogram (Lomb 1976; Scargle 1982) is computed on the $\text{PS}\otimes\text{PS}$ spectrum for the frequency range of the excited envelope. For the example star, KIC 6116048, the $\text{PS}\otimes\text{PS}$ can be seen in the bottom panel of Figure 2. A Gaussian is then fit to the periodogram, with the Gaussian's center corresponding to $\Delta\nu/2$. The $\ell = 1$ peak falls between the $\ell = 0$ peaks and so the power maximizes at $\Delta\nu/2$ instead of at $\Delta\nu$. To help fit the Gaussian, and determine the correct peak in the $\text{PS}\otimes\text{PS}$, we estimate $\Delta\nu_{\text{expected}}$ using our calculated value of ν_{max} . Many studies have shown a relationship where $\Delta\nu \propto \nu_{\text{max}}^\beta$, where β is between about 0.7 and 0.8 (see, e.g., Hekker et al. 2009; Stello et al. 2009; Huber et al. 2011; Yu et al. 2018), which allows us to determine which of the peaks in the $\text{PS}\otimes\text{PS}$ corresponds to $\Delta\nu/2$. The uncertainty in the location of the peak is determined using the standard deviation of grouped data as in Hekker et al. (2010):

$$s = \sqrt{\frac{\sum fx^2 - \frac{(\sum fx)^2}{\sum f}}{\sum f - 1}}, \quad (5)$$

where f is the bin height, x is the frequency, and the summation includes the bins around the peak that have a height $\geq 1\%$ of the peak's height. In the remainder of the paper we will refer to the seismic parameters determined using the ACF method as $\nu_{\text{max,ACF}}$ and $\Delta\nu_{\text{ACF}}$.

2.2.2. Determining Seismic Parameters Using the Coefficient of Variation Method

While the 2D autocorrelation method has been shown to provide reliable measurements of seismic parameters it can be computationally time consuming. To obtain another set of ν_{max} and $\Delta\nu$ measurements for our data we also determined the seismic parameters using a more efficient technique. The recent work of Bell et al. (2019) has shown that ν_{max} can be quickly determined using what is called the coefficient of variation, or CV. The coefficient of variation is the ratio of the standard

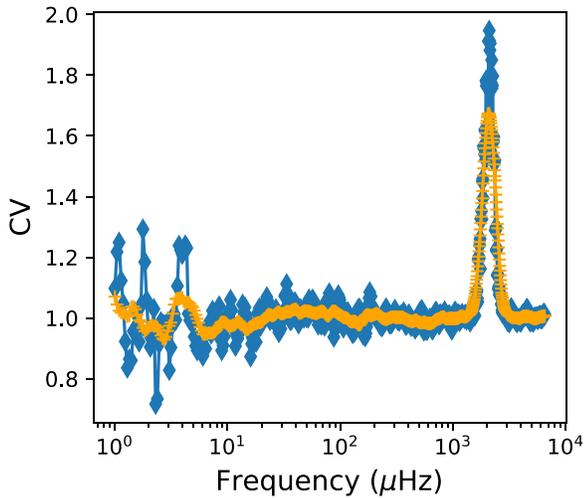

Figure 3. Coefficient of variation for KIC 6116048. The blue diamonds show the CV value for each window, and the yellow points show the smoothed trend.

deviation to the mean of the power spectrum. The basic premise is that in a power spectrum of pure noise, this ratio should be about 1. Thus, examining where in the power spectrum this ratio is greater than 1 can be used to determine the location of solar-like oscillations.

Our implementation of the CV method to determine ν_{\max} and the frequency range of the excited p-mode envelope is as follows. First, the power spectrum is broken up into a series of segments and the CV value is calculated for each segment. Starting with a window centered at $1 \mu\text{Hz}$, the window size is set to be the same as the estimated value of $\Delta\nu$ if the central frequency were assumed to be the value of ν_{\max} . This is done to ensure that the window size is large enough so that if there were oscillations present, some would fall within the window. The $\Delta\nu_{\text{estimate}}$ value is calculated assuming that $\Delta\nu_{\text{estimate}} = 0.267\nu_{\max}^{0.764}$ as in Yu et al. (2018). With the window size for this central frequency defined, the CV ratio is calculated for this window. The central frequency then shifts to higher frequencies by one-sixth of the previous window size. A new window size is calculated based on the new central frequency and the CV value is found again. The process is repeated until the end of the power spectrum is reached. The CV value for each window can be seen as the blue diamond points in Figure 3.

Next, the CV values from the different overlapping windows are smoothed. For each central frequency (each blue point in Figure 3) the width of the smoothing window is given by $0.66\nu_{\text{central}}^{0.88}$ (referred to as W_{Mosser} in the remainder of the paper), based on the FWHM of the excited mode envelope from Mosser et al. (2012). The CV values within this window are then averaged together. The resulting smoothed CV trend can be seen as the yellow points in Figure 3. The location of the highest smoothed value (the highest yellow point in Figure 3) is used as the initial estimate of ν_{\max} . From this initial $\nu_{\max, \text{estimate}}$, a weighted mean is performed, using the points that are within a window of $0.66\nu_{\max, \text{estimate}}^{0.88}$, to determine the true value of ν_{\max} . The weighted mean of the peak is calculated by

$$\text{Peak Centroid} = \frac{\sum_{i=1}^j \nu_i \times \text{CV}(\nu_i)}{\sum_{i=1}^j \text{CV}(\nu_i)}, \quad (6)$$

where ν is the frequency, $\text{CV}(\nu)$ is the smoothed CV value at that frequency, and j is the number of frequency bins that are

within the window defined by $0.66\nu_{\max, \text{estimate}}^{0.88}$. The uncertainty in ν_{\max} was again calculated using the standard deviation of grouped data, Equation (5).

The value of $\Delta\nu$ was then calculated in a manner similar to the method used in the 2D autocorrelation approach. A Gaussian was fit to the smoothed CV ν_{\max} peak, and the envelope of excited p-modes was determined to be the frequency range where the value was at least 10% of the peak height. A Lomb–Scargle periodogram was then computed on the power spectrum for this frequency range, following the traditional $\text{PS} \otimes \text{PS}$ method of determining $\Delta\nu$ (see, e.g., Hekker et al. 2010; Mathur et al. 2010). As previously described in Section 2.2.1, a Gaussian was then fit to the peak in the periodogram, where the Gaussian’s center corresponds to $\Delta\nu/2$. As before, the uncertainty in the location of the peak is determined using the standard deviation of grouped data as in Hekker et al. (2010). The seismic parameters determined using the CV method will be referred to as $\nu_{\max, \text{CV}}$ and $\Delta\nu_{\text{CV}}$ for the remainder of the paper.

It should be noted that our implementation of the CV method is not identical to that of Bell et al. (2019). This is necessary because the Bell et al. (2019) CV method was designed for red giant stars, using long-cadence light curves, while our sample also contains main-sequence and subgiant stars that have short-cadence data. For example, Bell et al. (2019) use 2000 overlapping bins spaced evenly in log-frequency (for their “oversampled” spectrum), while we implement the moving window overlapping by an amount based on the previous window size. This allows our windows to behave in the same manner regardless of whether we are using long or short-cadence data. Since our implementation is different, the parameter choices that we used were tested (see the Appendix) to ensure that we were determining the location of ν_{\max} correctly. For example, we examine the impact of changing the window size and smoothing size. As can be seen in the Appendix, the CV method described in this section provided the best ν_{\max} values.

2.3. Comparing $\Delta\nu$ Results

Since the ACF and CV methods define the frequency range of the excited p-mode envelope slightly differently, the resulting $\Delta\nu$ value from the $\text{PS} \otimes \text{PS}$ will be affected. Figure 4 shows the difference between $\Delta\nu_{\text{CV}}$ and $\Delta\nu_{\text{ACF}}$. As can be seen in Figure 4, the value of $\Delta\nu_{\text{CV}}$ tends to be slightly lower than the value of $\Delta\nu_{\text{ACF}}$; however, the values of $\Delta\nu$ from the two methods are in excellent agreement, with the difference being less than 0.5% for the vast majority of stars, and less than 1.5% in all cases. The spread in the difference between the values of $\Delta\nu_{\text{CV}}$ and $\Delta\nu_{\text{ACF}}$ is less than the spread when comparing our $\Delta\nu$ values to those in the literature (as seen in Figure 5). It should also be noted that the CV method offers a significant speed advantage over the ACF method.

Additionally, we can compare the value of $\Delta\nu$ determined using the CV method to the value of $\Delta\nu$ from the literature for our set of stars. For the comparison, values of $\Delta\nu$ for our sample of stars were obtained from Lund et al. (2017), Davies et al. (2016), Appourchaux et al. (2012), Huber et al. (2013), Bellamy & Stello (2015), and Bellamy (2015). A histogram of the fractional difference between our calculated value of $\Delta\nu_{\text{CV}}$ and the corresponding literature value of $\Delta\nu$ can be seen in Figure 5. As can be seen in Figure 5, our calculated values of $\Delta\nu$ agree very well with the literature values of $\Delta\nu$. Over 94%

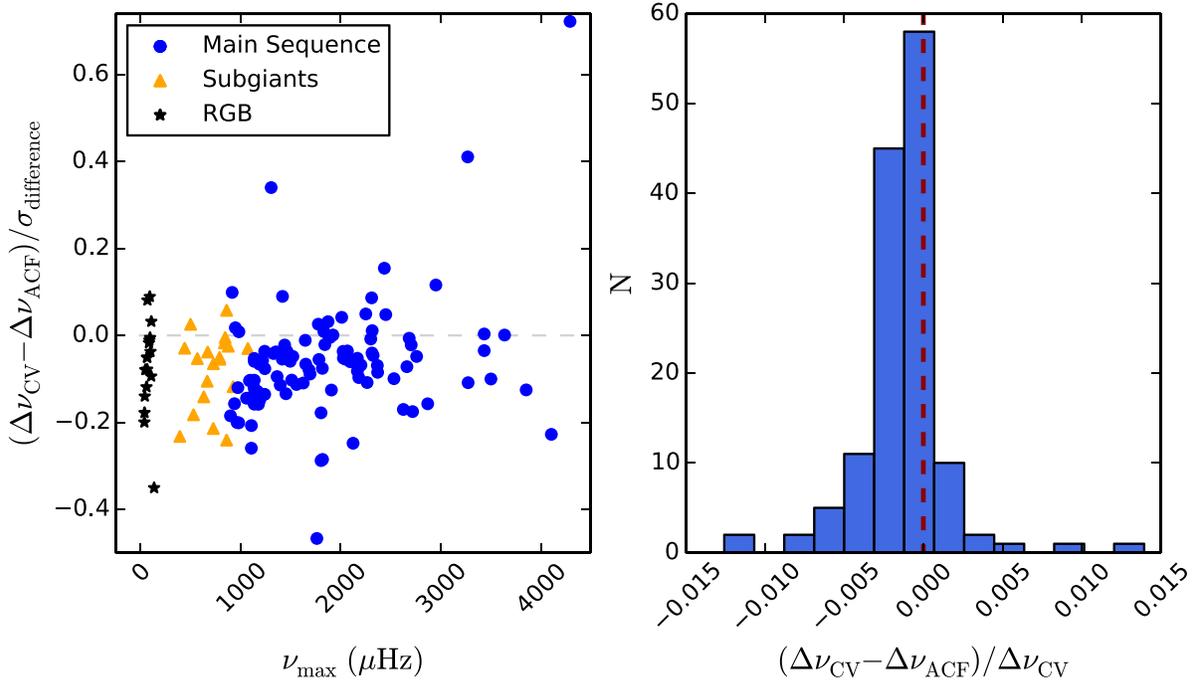

Figure 4. Difference between $\Delta\nu_{CV}$ and $\Delta\nu_{ACF}$ normalized by the uncertainty, $\sigma_{\text{difference}}$ (left). $\sigma_{\text{difference}}$ is the propagated uncertainty for the value of $\Delta\nu_{CV} - \Delta\nu_{ACF}$. The black points show the RGB stars, the orange triangles are the subgiants, and the blue circles are the main-sequence stars. The right panel shows a histogram of the fractional difference between $\Delta\nu_{CV}$ and $\Delta\nu_{ACF}$ for all the stars in the sample. The red dashed line marks 0 difference.

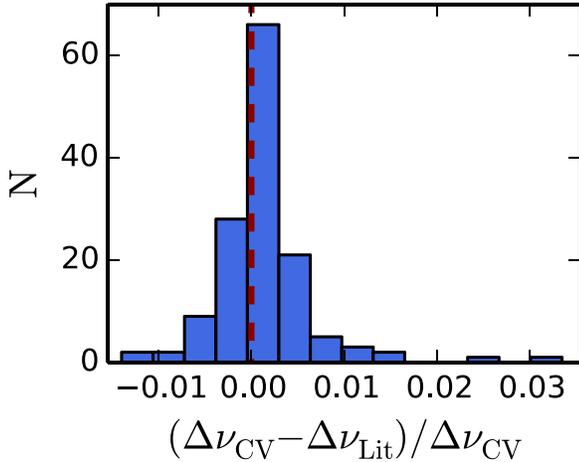

Figure 5. Fractional difference between $\Delta\nu$ calculated using the CV method and $\Delta\nu$ from the literature for our sample of stars. The red dashed line marks 0 difference.

of the stars have calculated values of $\Delta\nu$ within 1% of their corresponding $\Delta\nu$ value in the literature, and the distribution is centered around zero. Even in the most extreme case, the difference in the value of $\Delta\nu$ is around 3%.

2.4. Testing the Seismic Parameter Extraction on Solar Data

Both the 2D autocorrelation method and the coefficient of variation method to extract seismic parameters were then tested using solar data. This exercise served as a check to ensure our methods of seismic parameter extraction were providing reasonable values for $\Delta\nu$ and ν_{max} and as a way to compare the two methods. The Solar data were obtained from the 1 minute cadence photometric observations from the VIRGO instrument (Fröhlich et al. 1995; Fröhlich et al. 1997) on the ESA/NASA spacecraft *SOHO*. A segment of VIRGO data was

used that was the same length as our *Kepler* data. Using the CV method, the values of ν_{max} and $\Delta\nu$ for the Sun were $3091.4 \pm 11.9 \mu\text{Hz}$ and $135.0 \pm 1.4 \mu\text{Hz}$, while for the 2D autocorrelation method the values of ν_{max} and $\Delta\nu$ were 3417.6 ± 81.6 and $135.5 \pm 1.5 \mu\text{Hz}$. The typical accepted values of $\nu_{\text{max},\odot}$ and $\Delta\nu_{\odot}$ are 3090 and $135.1 \mu\text{Hz}$ (e.g., see Huber et al. 2011). The value of $\Delta\nu_{\odot}$ for both the 2D ACF method and the CV method are in good agreement with the accepted value of $\Delta\nu_{\odot}$, with the CV method’s value being slightly closer to the accepted $\Delta\nu_{\odot}$. Looking at the $\nu_{\text{max},\odot}$ value, while the CV $\nu_{\text{max},\odot}$ value is in good agreement with the accepted value, the 2D ACF $\nu_{\text{max},\odot}$ value is too large. While the focus of the paper is on measurements of $\Delta\nu$, obtaining the correct value of ν_{max} is important as the value of ν_{max} can in some cases affect the calculation of $\Delta\nu_{\text{freq}}$ (see Section 2.5). Therefore, due to our inability to reproduce $\nu_{\text{max},\odot}$ using our ACF prescription, along with the fact that it is time consuming, we use the seismic parameters determined using the CV method for the remainder of this work.

2.5. Determining $\Delta\nu$ from Individual Mode Frequencies

Since the goal of this work is to compare the value of $\Delta\nu_{CV}$ to $\Delta\nu_{\text{freq}}$, we also must calculate the large separation using the individual mode frequencies for these stars. Observed individual mode frequencies for the Lund et al. (2017), Davies et al. (2016), and Appourchaux et al. (2012) stars were obtained from the corresponding publications. For the NGC 6791 red giant stars the individual mode frequencies were determined by peak-bagging using the DIAMONDS code⁶ (Corsaro & De Ridder 2014) and the methodology for red giants (Corsaro et al. 2015), for a sample of cluster red giants from Corsaro et al.

⁶ Software and DIAMONDS code description are available at <https://github.com/EnricoCorsaro/DIAMONDS>.

Table 1
A Summary of the Various Different Methods Used to Calculate $\Delta\nu_{\text{freq}}$

Method	Weighting Used in Slope Determination	Number of Frequencies Used
I	None	Full Set of Observed Modes Used
II	Error Weighted	Full Set of Observed Modes Used
III	Gaussian with an FWHM of $0.66\nu_{\text{max}}^{0.88}$ (Mosser et al. 2012)	Full Set of Observed Modes Used
IV	None	4 Total, 2 on Each Side of ν_{max}
V	Error Weighted	4 Total, 2 on Each Side of ν_{max}
VI	None	10 Total, 5 on Each Side of ν_{max}
VII	Error Weighted	10 Total, 5 on Each Side of ν_{max}

(2017a). The DIAMONDS code determines parameters using a nested sampling Monte Carlo algorithm.

From the individual mode frequencies $\Delta\nu_{\text{freq}}$ can be calculated by determining the slope of the line of best fit for a plot of frequency versus n for modes of the same ℓ . The issue, however, is that performing this fit in different ways will alter the values of $\Delta\nu_{\text{freq}}$. For example, the slope of the line will be different depending on which ℓ modes are being used. Additionally, there is the question if there should be any weighting on the frequencies. Should modes closer to ν_{max} be more heavily weighted? Should the modes be weighted by their uncertainties? Should only modes closest to ν_{max} be used? All of these options will result in a different value of $\Delta\nu_{\text{freq}}$.

In the literature there are many different methods used to determine the value of $\Delta\nu$ from individual mode frequencies. For example, Handberg et al. (2017) calculated the average $\Delta\nu$ by weighting the frequencies by their observational errors. Other studies have implemented some type of Gaussian weighting around ν_{max} (White et al. 2011; Rodrigues et al. 2017). Hekker et al. (2013) used both a Gaussian-weighted linear fit, an unweighted fit, as well as the median of the pairwise differences of the modes. It is also possible to just use the modes closest to ν_{max} , for example, Corsaro et al. (2017b) determined $\Delta\nu$ using a Bayesian linear regression on the asymptotic relation using the central 3 $\ell = 0$ mode frequencies.

For each star in our sample, we calculate $\Delta\nu_{\text{freq}}$ in seven different ways for each ℓ . So, for stars with $\ell = 0, 1$, and 2 values, then $\Delta\nu_{\text{freq}}$ was calculated 21 different times. The different methods of determining $\Delta\nu$ are summarized in Table 1 and explained in more detail as follows:

- I. *No Weighting*: The best-fit slope of the frequency versus n plot is simply calculated without taking any weighting or uncertainties into account. The full set of observed modes for a given ℓ is used.
- II. *Error Weighting*: The best-fit slope takes into account the uncertainties in the observed frequency values. The full set of observed modes for a given ℓ is used.
- III. *Gaussian Weighting*: High signal-to-noise data show that the power envelope of the excited modes is a Gaussian with an FWHM of $0.66\nu_{\text{max}}^{0.88}$ (Mosser et al. 2012). Therefore, it may be reasonable to weight those modes closer to ν_{max} more heavily in the best-fit slope. Here each frequency is given a weight, where the weighting function is a Gaussian centered on ν_{max} with an FWHM given by $0.66\nu_{\text{max}}^{0.88}$. The weight, W , for each point is then given by

$$W = e^{-(\nu - \nu_{\text{max}})^2 / (2\sigma^2)}, \quad (7)$$

where $\sigma = \text{FWHM} / (2\sqrt{2\ln(2)})$. This is similar to what was done in Rodrigues et al. (2017), with the difference

being the value of σ used. Rodrigues et al. (2017) use $\sigma = 0.66\nu_{\text{max}}^{0.88}$, while we use that as our FWHM, thus making our values of σ differ by a factor of $2\sqrt{2\ln(2)}$. With the weighting for each frequency determined, the slope of the line of best fit is then calculated by minimizing

$$\sum_{i=1}^k W_i [\nu_i - (\text{slope} \times n_i + \text{intercept})]^2, \quad (8)$$

where k is the number of modes. The full set of observed modes for a given ℓ is used.

- IV. *No Weighting, 4 Points*: Only 4 frequencies are used in the fit, 2 on each side of ν_{max} . No errors or weighting equation is used.
- V. *Error Weighting, 4 Points*: Only 4 frequencies are used in the fit, 2 on each side of ν_{max} . The uncertainties in the observed frequencies are included in the best-fit slope calculation.
- VI. *No Weighting, 10 Points*: Only 10 frequencies are used in the fit, 5 on each side of ν_{max} . No errors or weighting equation is used.
- VII. *Error Weighting, 10 Points*: Only 10 frequencies are used in the fit, 5 on each side of ν_{max} . The uncertainties in the observed frequencies are included in the best-fit slope calculation.

For each star, and for each ℓ , these seven methods were used to compute $\Delta\nu_{\text{freq}}$. For the remainder of the paper the methods will be referred to by their corresponding Roman numeral. Note that when determining the individual mode frequencies in actual stellar models then methods II, V, and VII cannot be used since there is no associated observational uncertainty on the frequencies.

3. Results

3.1. Comparing $\Delta\nu_{\text{CV}}$ and $\Delta\nu_{\text{freq}}$

The large frequency spacing calculated using the CV method, $\Delta\nu_{\text{CV}}$, can be compared to the different values of $\Delta\nu_{\text{freq}}$ calculated in Section 2.5. Figure 6 shows the difference between the values of $\Delta\nu_{\text{freq}}$ and $\Delta\nu_{\text{CV}}$ divided by the uncertainty in the difference, as a function of ν_{max} , for each different method of calculating $\Delta\nu_{\text{freq}}$ for the $\ell = 0, 1$, and 2 modes. As can be seen in Figure 6, the difference between the values of $\Delta\nu$ are mostly all within 1σ . The exception to this is $\Delta\nu$ calculated with the $\ell = 1$ modes in the subgiant stars, which have a large scatter. This is due to the fact that the subgiant stars have mixed-modes. For the sake of making the ordinate scale in Figure 6 small enough to easily view the data, some of the values of $\Delta\nu$ calculated using the $\ell = 1$ frequencies for the subgiant stars fall outside the range of the figure and are not visible. Additionally,

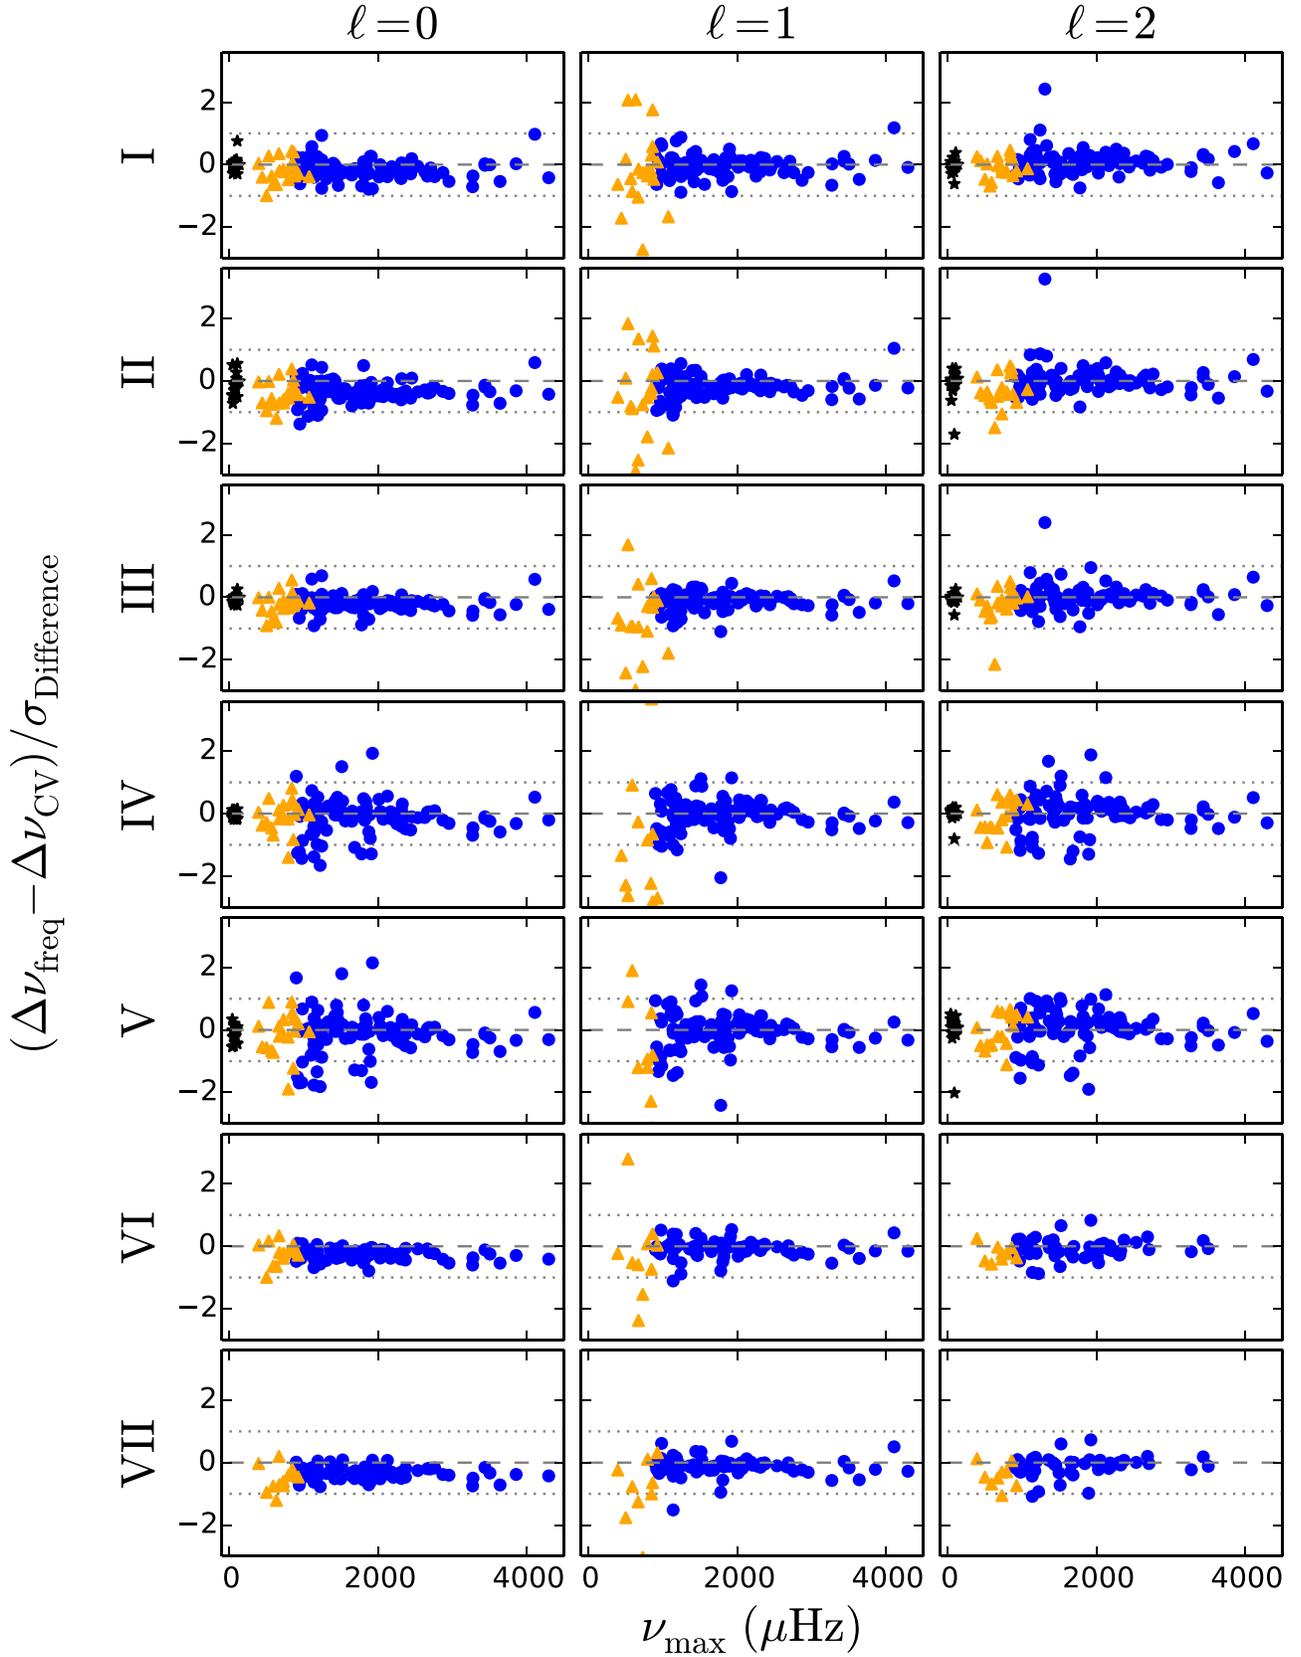

Figure 6. The difference, $(\Delta\nu_{\text{freq}} - \Delta\nu_{\text{CV}}) / \sigma_{\text{Difference}}$, as a function of ν_{max} for each of the different methods of determining $\Delta\nu_{\text{freq}}$ and for each ℓ . Note that some of the subgiant stars are not in the ordinate range of this plot. Colors are the same as Figure 4. For reference, the dashed line is at 0, and the dotted lines are at ± 1 .

one should note that for the RGB stars there were not enough modes on either side of ν_{max} for the value of $\Delta\nu_{\text{freq}}$ to be calculated using methods VI and VII.

It can also be seen in Figure 6 that there is a larger scatter and disagreement for the method of determining $\Delta\nu_{\text{freq}}$ using only two frequencies on either side of ν_{max} (methods IV and

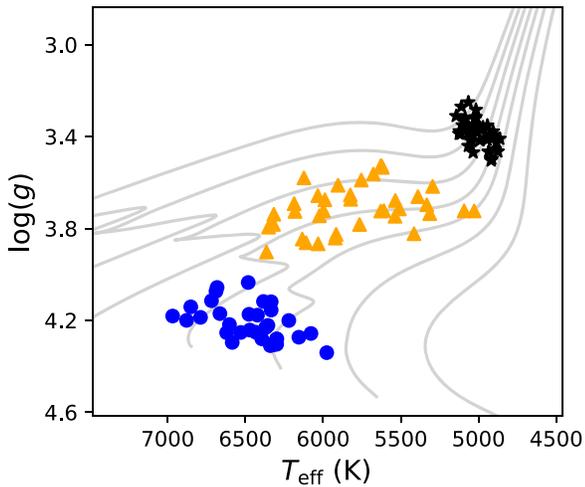

Figure 7. Kiel diagram of the stars selected from Ball et al. (2018). The black points are the red giant stars, the orange triangles are the subgiant stars, and the blue circles are the main-sequence stars. The background gray lines show tracks of mass 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, and 2.0 M_{\odot} , created using YREC (Demarque et al. 2008).

V). This suggests that using only four frequencies in the $\Delta\nu$ determination is not ideal when attempting to match the value of $\Delta\nu$ one would calculate from the observed power spectrum. This larger scatter makes sense due to the fact that the value of $\Delta\nu_{CV}$ uses nearly the entire region of oscillations from the power spectrum and therefore takes many more than four frequencies into account. So, one might expect that the value of $\Delta\nu_{CV}$ and $\Delta\nu_{freq}$ would match more poorly when $\Delta\nu_{freq}$ only uses a few modes.

Additionally, for some of the methods it does appear that the value of $\Delta\nu_{freq}$ tends to be smaller than the value of $\Delta\nu_{CV}$. This can be seen in Figure 6 for the $\ell = 0$ modes in methods II, III, VI, and VII as well as the $\ell = 1$ and $\ell = 2$ modes for method VII. Despite the differences among the methods, with exception to some of the subgiant stars, the values of $\Delta\nu_{CV}$ and $\Delta\nu_{freq}$ agree to within a few percent.

3.2. Simulated TESS Data

So far our comparisons have used observed data with the determined mode frequencies acting as a proxy for the frequencies one would have from a stellar model. Since the properties of the observations, for example, the signal-to-noise ratio or time-series length, will determine which modes were observed, we need to make sure that our results also hold when using stellar models. Additionally, since the goal of this project is to determine the best method of calculating $\Delta\nu$ from stellar models, it is critical that we repeat the experiment using frequencies from actual stellar models. To accomplish this, we make use of the simulated *TESS* data from Ball et al. (2018). Ball et al. (2018) created a mock catalog of light curves to simulate data from NASA’s *TESS* (Ricker et al. 2015). From this mock catalog we selected 34 main-sequence stars, 37 subgiants, and 47 red giants to analyze. The selected stars can be seen in the Kiel diagram in Figure 7. Note that the Ball et al. (2018) simulated *TESS* data were restricted to stars that would be observed with the short-cadence (2 minute) mode of *TESS*, and as a result the red giant stars available in this catalog are those that are not evolved too far along the red giant branch. All of the selected stars and light curves used are from “Sector 1” in Ball et al. (2018). Additionally, it should be noted that the light curves used did not have white noise added to them.

While Ball et al. (2018) provide the expected value of the white noise for each light curve, the scope of this project is not concerned with the actual observing capabilities of *TESS*, rather the comparison between the value of $\Delta\nu$ from the power spectrum and $\Delta\nu$ from frequencies. Hence, the clean light curves from Ball et al. (2018) were used without added noise.

From the simulated *TESS* data, the “observed” values were calculated from the light curves. The values of ν_{max} and $\Delta\nu_{CV}$ were calculated using the coefficient of variation method as discussed in Section 2.2.2. For the simulated stars Ball et al. (2018) also model each star and provide individual mode frequencies. It should be noted that the frequencies from the models were used in the creation of the simulated spectra. So, unlike typical model frequencies that may disagree with the true frequency values, these modeled frequencies are actually those found in the simulated spectra. Using these model frequencies, the value of $\Delta\nu_{freq}$ was calculated as discussed in Section 2.5. The frequencies provided from the Ball et al. (2018) models are for values between 0.15 and 0.95 ν_{ac} . Thus, for the model stars, when calculating $\Delta\nu_{freq}$ using methods I and III, which utilize the full set of modes, this corresponds to all modes between 0.15 and 0.95 ν_{ac} .

As in Section 3.1, we then compare the values of $\Delta\nu_{CV}$ and $\Delta\nu_{freq}$. Figure 6 can be remade, but for the sample of stars from the simulated *TESS* data. This can be seen in Figure 8. Note that methods II, V, and VII are not used in this case. This is due to the fact that these methods use the observational uncertainties when determining the value of $\Delta\nu_{freq}$ and the model values do not have observational uncertainties. As seen in Figure 8, again the values of $\Delta\nu_{CV}$ and $\Delta\nu_{freq}$ agree well and for the most part are within 1σ or 2σ . Additionally, it can be seen that for method I the value of $\Delta\nu_{freq}$ tends to be smaller than the value of $\Delta\nu_{CV}$.

4. Discussion

We can put the information in Figures 6 and 8 on a more quantitative footing to determine which method of calculating $\Delta\nu_{freq}$ is most in agreement with the value of $\Delta\nu_{CV}$. The root mean square (rms) value of the percent difference, $100 \times (\Delta\nu_{freq} - \Delta\nu_{CV}) / \Delta\nu_{CV}$, can be compared for each method of calculating $\Delta\nu_{freq}$. Table 2 shows the rms value for each method of calculating $\Delta\nu_{freq}$ for each set of stars for the observed sample. As can be seen in Table 2, the best method to calculate $\Delta\nu_{freq}$ depends on the star’s evolutionary stage and the ℓ of interest.

For the main-sequence stars using the $\ell = 0$ modes, methods I, III, and VI perform equally well and produce values of $\Delta\nu_{freq}$ closer to the values of $\Delta\nu_{CV}$ than the other methods. Using the $\ell = 1$ modes instead, methods I, III, and VI again outperform the other methods, with method VII being equally good as well. When using only the $\ell = 2$ modes methods VI and VII perform equally well and better than the other methods. However, we must be careful with comparing all the methods at once, since not every star in the sample can be included in every method of calculating $\Delta\nu_{freq}$. For example, not all the stars had enough observed modes to use methods VI and VII. Since all the stars are included in methods I, II, and III, then it is safest to compare these three against each other. Doing this we see that for the main-sequence stars using the $\ell = 0$ or $\ell = 1$ modes are much better than using the $\ell = 2$ modes. Also, we see that using methods I and III are nearly equivalent and better than method II. So, this means that for the main-sequence stars using

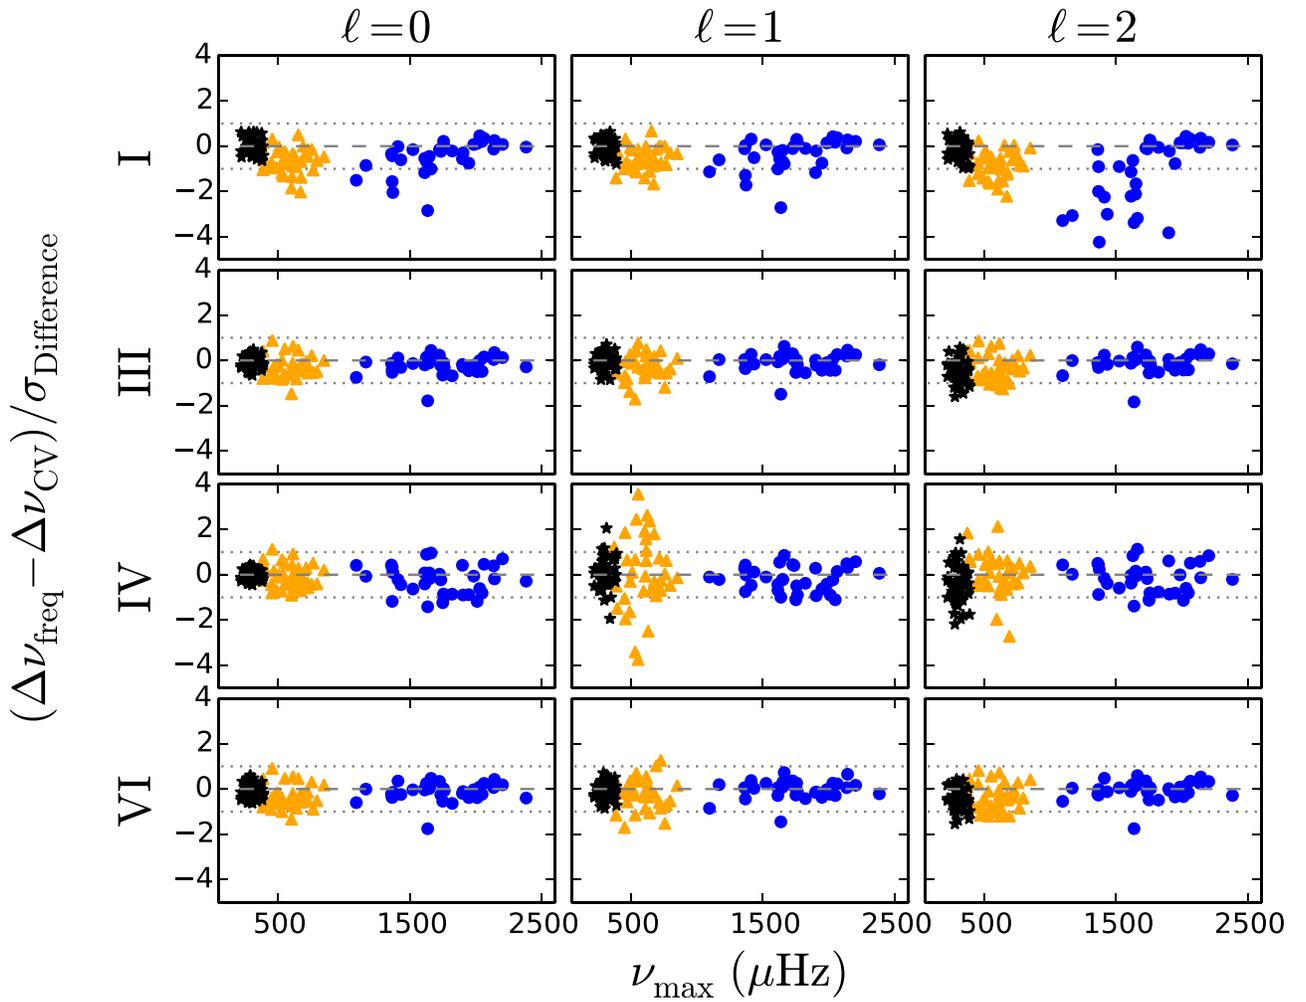

Figure 8. The difference, $(\Delta\nu_{\text{freq}} - \Delta\nu_{\text{CV}})/\sigma_{\text{Difference}}$, as a function of ν_{max} for each of the different methods of determining $\Delta\nu_{\text{freq}}$ and for each ℓ for stars from the *TESS* simulated data. Colors are the same as Figure 4. For reference, the dashed line is at 0, and the dotted lines are at ± 1 .

either no weighting or the Mosser et al. (2012) Gaussian weighting is better than weighting by the observational uncertainties.

For the subgiant stars, using the $\ell = 0$ modes, methods I, III, and VI perform nearly equivalently and are better than the other methods. The $\ell = 1$ modes do not provide good values, as expected due to the presence of mixed-modes. For the $\ell = 2$ modes, all the methods perform about the same, except for methods I and VII being worse.

For the red giant stars, using the $\ell = 0$ modes, method III is the best; however, all methods except II do equally well. Note that methods VI and VII are not included for the RGB stars because there were not enough modes to have five frequencies on each side of ν_{max} . Using the $\ell = 2$ modes, methods I and III perform equally well and better than the other methods. For every method, using the $\ell = 0$ modes provided the best results for the RGB stars. Similar to the main-sequence stars, we see that using either no weighting or the Mosser et al. (2012) Gaussian weighting is better than using the observational uncertainties.

We can perform the same investigation for the simulated *TESS* data, again looking at the rms value of the percent difference, $100 \times (\Delta\nu_{\text{freq}} - \Delta\nu_{\text{CV}})/\Delta\nu_{\text{CV}}$, for each method. Table 3 shows the rms value for each method of calculating $\Delta\nu_{\text{freq}}$ for each set of stars and each ℓ . There are a few

important differences to note with using the simulated *TESS* data compared to the observational data. First of all, for the simulated *TESS* data, we only selected the $\ell = 1$ modes that were not mixed-modes. So, the rms values of the subgiant $\ell = 1$ modes are unrealistically good. Additionally, since the mode frequencies are from models, we have many more modes than we would actually have from observations for these stars. This also means that all of the stars in our sample of simulated *TESS* data had enough modes that all stars could be put through each method of calculating $\Delta\nu_{\text{freq}}$ for every ℓ . However, since the modes are from stellar models, methods II, V, and VII could not be calculated since there was no observational uncertainty on the modes.

As can be seen in Table 3, for the main-sequence stars, when using the $\ell = 0$ modes, methods III and VI perform nearly equally well and better than the other methods. Methods III and VI again outperform the others when using the $\ell = 1$ modes or the $\ell = 2$ modes as well. When comparing using the $\ell = 0$ and $\ell = 2$ modes for the main-sequence stars we see that for methods III, IV, and VI the resulting rms values are very similar. For method I using the $\ell = 0$ modes is better than using the $\ell = 2$ modes.

For the subgiant stars methods III and VI are slightly better for the $\ell = 0$ modes. For the $\ell = 1$ and $\ell = 2$ modes method III

performs the best. For every method, using the $\ell = 0$ modes for the subgiants outperforms using the $\ell = 2$ modes.

For the red giant branch stars, regardless of which method is being used, using the $\ell = 0$ modes give a lower rms value than using the $\ell = 1$ or $\ell = 2$ modes. Additionally, regardless of which ℓ modes are being used, method I is the best in all cases. However, since for these simulated stars we have a lot more modes than we would get in observations, then perhaps using all available frequencies as in method I is unrealistic. If instead for the RGB stars we are restricted to only using five points on either side of ν_{max} , as in method VI, then the resulting rms values are either better or nearly the same as using the Gaussian weighting of method III.

Finally, for our observed RGB stars we can compare our $\nu_{\text{max,CV}}$ and $\Delta\nu_{\text{CV}}$ values to those from Corsaro et al. (2017b). Corsaro et al. (2017b) determined $\Delta\nu$ using a Bayesian linear regression on the asymptotic relation using the central 3 $\ell = 0$ mode frequencies. We see that the values of $\Delta\nu$ agree to within 1.5% and values of ν_{max} agree to within 10%. Comparing the values of $\Delta\nu_{\text{freq}}$ to the $\Delta\nu$ values from Corsaro et al. (2017b) we see that for the $\ell = 0$ modes, method V is in the most agreement. This is as expected since method V uses two points on each side of ν_{max} with error weights and is the most similar method compared to the technique of using the three central frequencies performed in Corsaro et al. (2017b).

5. Summary and Conclusion

When comparing observed values of $\Delta\nu$ to values of $\Delta\nu$ calculated from stellar models, we must be aware that the manner in which these two values of $\Delta\nu$ are being determined is different. The observed value of $\Delta\nu$ from photometric time-series data is typically determined using autocorrelation techniques or PS \otimes PS methods, while this is not the case when calculating $\Delta\nu$ from stellar models. In stellar models the actual individual mode frequencies are calculated and then the value of $\Delta\nu_{\text{freq}}$ can be determined by fitting a line to the frequency versus n data. There are many different methods by which to

perform this linear fit, for example, to weight the frequencies closer to ν_{max} more heavily, to only use a few points around ν_{max} , and deciding which ℓ modes to include. It is critical that when we determine the value of $\Delta\nu$ for stellar models that we are doing so in a way that will provide consistent results with the values of $\Delta\nu$ calculated through observations. Otherwise, the comparison between the two values of $\Delta\nu$ loses accuracy.

In this work we took high signal-to-noise *Kepler* observations and determined the seismic parameters using standard methods. Each of these stars also had individual mode frequencies determined in the literature. Using these individual mode frequencies as a proxy for the frequencies one would have from modeling a star, we determined $\Delta\nu_{\text{freq}}$ in several different ways to compare to the value of $\Delta\nu_{\text{CV}}$. We also made use of simulated *TESS* light curves and stellar models to compare the methods of calculating $\Delta\nu$ values. From the results of comparing $\Delta\nu_{\text{CV}}$ and $\Delta\nu_{\text{freq}}$ both from the observed stars and the simulated *TESS* data, we show that using the $\ell = 0$ modes with either no weighting or a Gaussian weighting as in Mosser et al. (2012) provides the best agreement. Additionally, we see that using the coefficient of variation method as in Bell et al. (2019) provides a quick and accurate way to identify the frequency range of excited modes.

Appendix Testing the Various CV Methods

As mentioned in Section 2.2.2, many variations of the CV method were tested. These different implementations of the CV method will be described here, where we refer to the method described in Section 2.2.2 as the “base” method. In the “base” method, each step we shift the window toward higher frequencies by one-sixth the previous window size. We also tested shifting the window by one-fourth, one-half, one-tenth, and one-twentieth of the previous window size. This effectively changes the density of the blue points in Figure 3. Also, we tested using different window sizes when calculating the CV value along the spectrum. In the base implementation the window size is determined by estimating the value of $\Delta\nu$ at the central frequency. We also tested window sizes of $2\Delta\nu$, $4.2\Delta\nu$, and W_{Mosser} . Additionally, when smoothing the CV values the size of the smoothing window was tested. In the base method we smoothed with a window of width W_{Mosser} and here we test using a window of width $2W_{\text{Mosser}}$, $W_{\text{Mosser}}/2$, $2\Delta\nu$, $4.2\Delta\nu$, $6\Delta\nu$, and $8\Delta\nu$. The final parameter that was tested was the window sizes used when determining the weighted centroid of the peak. In the base implementation we use a window of W_{Mosser} and here we also test a window of $2W_{\text{Mosser}}$.

To test which method works best a set of 63 randomly selected red giant stars from the Second APOKASC Catalog (Pinsonneault et al. 2018) was used. Using the power spectrum from KASOC, the ν_{\max} values of the 63 stars were calculated using the base CV method as described in Section 2.2.2. Then the various different implementations of the CV method, described in the previous paragraph, were used to again calculate ν_{\max} . The resulting ν_{\max} values were compared to the values of ν_{\max} from the Second APOKASC paper (Pinsonneault et al. 2018), as well as the different pipelines in the Second APOKASC Catalog: A2Z (Mathur et al. 2010; García et al. 2014), CAN (Kallinger et al. 2010), COR (Mosser & Appourchaux 2009), OCT (Hekker et al. 2010), and SYD (Huber et al. 2009). The rms value for the percent difference, $100 \times (\nu_{\max, \text{pipeline}} - \nu_{\max, \text{CV}}) / \nu_{\max, \text{CV}}$, was calculated for each CV implementation and can be seen in Table 4. While the “best” method depends on which pipeline the

ν_{\max} value is being compared to, the base CV method was in good agreement across all sets. Additionally, if the rms values for the pipelines are averaged together, as seen in the last column of Table 4, then the base CV method performs the best. Therefore, this base method was the one selected as the best implementation of the CV method and is the one used throughout the paper.
