ABSTRACT

We combine photometry from the Ultra Deep Survey (UDS), Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS) UDS and CANDELS the Great Observatories Origins Deep Survey-South (GOODS-S) surveys to construct the galaxy stellar mass function probing both the low- and high-mass end accurately in the redshift range $0.3 < z < 3$. The advantages of using a homogeneous concatenation of these data sets include meaningful measures of environment in the UDS, due to its large area (0.88 deg^2), and the high-resolution deep imaging in CANDELS ($H_{160} > 26.0$), affording us robust measures of structural parameters. We construct stellar mass functions for the entire sample as parametrized by the Schechter function, and find that there is a decline in the values of ϕ and of α with higher redshifts, and a nearly constant M^* up to $z \sim 3$. We divide the galaxy stellar mass function by colour, structure, and environment and explore the links between environmental overdensity, morphology, and the quenching of star formation. We find that a double Schechter function describes galaxies with high Sérsic index ($n > 2.5$), similar to galaxies which are red or passive. The low-mass end of the $n > 2.5$ stellar mass function is dominated by blue galaxies, whereas the high-mass end is dominated by red galaxies. This shows that there is a possible link between morphological evolution and star formation quenching in high mass galaxies, which is not seen in lower mass systems. This in turn suggests that there are strong mass-dependent quenching mechanisms. In addition, we find that the number density of high-mass systems is elevated in dense environments, suggesting that an environmental process is building up massive galaxies quicker in over densities than in lower densities.

Key words: galaxies: evolution – galaxies: formation – galaxies: luminosity function, mass function – galaxies: structure.

1 INTRODUCTION

The galaxy stellar mass function (galaxy SMF) is an important tool for exploring galaxy evolution and the growth of stellar mass over cosmic time. By investigating the galaxy SMF of different populations we can begin to understand the physical processes

*E-mail: alicem@roe.ac.uk

[†]Scottish Universities Physics Alliance

which govern stellar mass growth as well as the types of galaxies affected by these physical processes. With the advent of surveys which cover large areas, e.g. the Cosmic Evolution Survey (COSMOS; Scoville et al. 2007), we are now able to study the galaxy SMF with respect to different galaxy properties.

Some of the first studies which investigated the galaxy SMF focused on the local Universe. Both Cole et al. (2001) and Bell et al. (2003) constructed the local galaxy SMF down to stellar masses of $M_* > 10^9 M_\odot$ by converting the *K*-band luminosity function. More recent studies have investigated the local galaxy SMF using stellar masses obtained from galaxy photometry (Li & White 2009; Baldry et al. 2012). These have pushed further down in stellar mass and computed the number densities of galaxies down to $M_* = 10^8 M_\odot$ and a good consensus has been reached on the shape of the local galaxy SMF.

Thanks to advances in technology, it is now possible to obtain large samples of galaxies for which redshifts and stellar masses can be computed. This has led to the exploration of the SMF across large ranges in redshift and stellar mass. Many of the earlier studies from the last decade have constructed the galaxy SMF up to redshifts of $z = 1-2$ (e.g. Fontana et al. 2004; Conselice, Blackburne & Papovich 2005; Borch et al. 2006; Bundy et al. 2006; Franceschini et al. 2006; Pannella et al. 2006). Other studies have pushed beyond this to measure the number densities of galaxies from $z = 0$ to redshifts of $z \sim 4-5$ (e.g. Drory et al. 2005; Fontana et al. 2006; Pérez-González et al. 2008) and higher (e.g. Yan et al. 2006; Stark et al. 2009; Caputi et al. 2011; González et al. 2011; Lee et al. 2012; Duncan et al. 2014). These studies have provided excellent constraints on the evolution of the galaxy SMF, often with deep data covering tens to hundreds of arcminutes squared.

In the last five years deeper data sets have facilitated better constraints on the low-mass slope of the galaxy SMF. Studies which probe stellar masses down to $M_* \sim 10^9 M_\odot$ at redshifts of $z \sim 1$ have found evolution in the low-mass slope of the galaxy SMF such that it becomes steeper at higher redshifts (Marchesini et al. 2009). Furthermore, several studies which probe the lowest mass populations have found that these systems are abundant and hence the low-mass slope is very steep even at redshifts of $z = 1$ (e.g. Kajisawa et al. 2009; Mortlock et al. 2011; Santini et al. 2012; Tomczak et al. 2014). Complementing these results are studies which use data from large area surveys which is vital for constraining the high-mass end of the galaxy SMF (e.g. Ilbert et al. 2010, 2013; Pozzetti et al. 2010; Davidzon et al. 2013; Moustakas et al. 2013; Muzzin et al. 2013; Tomczak et al. 2014). The high-mass turnover appears to evolve very little with redshift.

Numerous investigations have elucidated the dependence of build-up of stellar mass on different parameters. The dependence of the galaxy SMF on a system's star formation (SF) properties (often determined by colour) can clearly tell us lots about how galaxies are growing. Early studies showed that the stellar mass distribution of star-forming and non-star-forming objects, or blue and red objects, is very different. At redshift of $z < 1$ red objects were found to dominate the high-mass end of the galaxy SMF whereas blue systems dominate the low-mass end (Borch et al. 2006; Bundy et al. 2006; Bell et al. 2007). The first studies which explored the low-mass end of the red SMF showed that the number densities of red low-mass systems evolve quickly, resulting in a bimodality at $z < 1$ (Drory et al. 2009) and higher (Ilbert et al. 2010). More recent studies have also found a bimodal form to the galaxy SMF of red galaxies, as well as surprisingly constant evolution in the SMF of blue systems (Mortlock et al. 2011; Baldry et al. 2012; Ilbert et al. 2013; Moustakas et al. 2013; Muzzin et al. 2013).

The environment in which the galaxy resides is also a key parameter which affects the build-up of galaxy stellar mass. A galaxy in a dense environment may interact with the surrounding galaxies and may build up stellar mass through mergers or be quenched via gas stripping or merger driven feedback. This in turn can affect galaxy properties such as morphology and structure (e.g. Dressler 1980; Bamford et al. 2009; Maltby et al. 2010; Skibba et al. 2012; Lani et al. 2013) or SF properties and colour (e.g. Cooper et al. 2007; van der Wel 2008; Chuter et al. 2011; Grützbauch et al. 2011a,b). However, it is difficult to discern whether it is the environmental processes or internal processes (e.g. *in situ* SF or feedback) which are driving mass growth and the truncation of SF. By constructing the galaxy SMF with respect to environment and SF history, it is possible to explore how both internal and external processes are driving the growth of galaxies of different stellar masses.

Measuring the environment of a galaxy is, however, a non-trivial problem which requires either a large survey area or targeted observations of cluster, group and field galaxies. Therefore there has only been a handful of work to date which examines the galaxy SMF in different environments (e.g. Balogh et al. 2001; Kodama & Bower 2003; Bundy et al. 2006; Bolzonella et al. 2010; Vulcani et al. 2011). The main conclusion of these studies is that the number densities of galaxies in the highest density regions are dominated by massive, early-type galaxies. This result is another way of exploring the already well-established morphology–density relation (Dressler 1980; Postman & Geller 1984; Treu et al. 2003; Nuijten et al. 2005; Postman et al. 2005; Holden et al. 2007).

Peng et al. (2010b) find that out to redshifts of $z \sim 1$ observations can be explained by the effects of environment and stellar mass being separable, and that these two effects halt SF in galaxies. The evolution of the shape of the galaxy SMF of star-forming and passive galaxies in the SDSS supports their proposed forms of quenching. Furthermore, the evolution of the UltraVISTA galaxy SMF of blue and red galaxies can also be explained as a mixture of mass and environment quenching (Ilbert et al. 2013). The United Kingdom Infrared Telescope (UKIRT) Infrared Deep Sky Survey (UKIDSS; Lawrence et al. 2007) Ultra Deep Survey (UDS) is the ideal data set to test the effect of environment on the galaxy SMF, as the large area covered ($\sim 1 \text{ deg}^2$) allows us to probe different galaxy environments.

The build-up of stellar mass in a galaxy also links with galaxy structure. Recent advances in observations allow us to probe galaxy structure at high redshift with high-resolution imaging. By investigating the galaxy SMF with respect to galaxy structure we can infer how the morphologies of galaxies change as a function of stellar mass and redshift. Furthermore, several studies have previously noted that there is strong correlation between the presence of a bulge and passivity (e.g. Bell et al. 2012; Bruce et al. 2012, 2014; Cheung et al. 2012; Barro et al. 2013; Fang et al. 2013; Lee et al. 2013; Lang et al. 2014; Williams et al. 2014). Although there is a significant passive disc population (e.g. McLure et al. 2013; Bruce et al. 2014) which questions whether or not the presence of a bulge causes passivity (or vice versa). We can therefore use the galaxy SMF divided by structural parameters, compared to that divided by colour, to further examine the possible link between the two.

Previously, studies have investigated the galaxy SMF using various selections which correlate with morphology using various classification methods. These include visual morphology (Conselice et al. 2005), automated methods (Franceschini et al. 2006; Pannella et al. 2006, 2009), and spectral type (Fontana et al. 2004; Vergani et al. 2008). In Pozzetti et al. (2010) a comparison between various classifications is performed and they found that there

is not always agreement between different methods of dividing systems by morphology. Nevertheless these studies all find that at $z < 1$ the massive end ($M_* > 10^{11} M_\odot$) of the galaxy SMF is dominated by the red, dead, and ‘well-fed’ systems with high Sérsic indices ($n > 2.5$). The low-mass systems are dominated by star-forming, blue, low Sérsic index ($n < 2.5$) systems. Furthermore, the morphological mix changes with redshift such that at higher redshift more and more of the ‘late-type’ objects dominate the stellar mass budget. Evidence for morphological division is also present in the K -band luminosity function. Devereux et al. (2009) reported evidence for the local number densities of bright objects being dominated by ellipticals and S0 galaxies, as well as fainter objects being dominated by disc-type galaxies. Further investigation is needed to understand how the shape of the galaxy SMF is changing for systems with different structure at high redshift. The high-resolution, near-infrared (IR) imaging from the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; PIs: Faber and Ferguson; Grogin et al. 2011; Koekemoer et al. 2011) provides excellent data to perform this study.

In this work we use the combined power of the UDS, CANDELS UDS and CANDELS the Great Observatories Origins Deep Survey-South (GOODS-S) data sets to explore the total galaxy SMF over several orders of magnitude in stellar mass up to redshifts of $z \sim 3$. In addition, we also explore the evolution of the galaxy SMF with respect to colour, environment, and structure, drawing on the strengths of our three different surveys to provide the most robust measure for each. This paper is set out as follows. Section 2 describes how we calculate redshifts, stellar masses, rest-frame colours, environment and structural parameters. Section 3.1 describes the total galaxy SMF from a combination of the UDS, CANDELS UDS and CANDELS GOODS-S data. Section 3.2 describes the galaxy SMF divided into passive and star-forming galaxies. Section 3.3 describes the galaxy SMF divided into high and low density in the UDS. Section 3.4 discusses the galaxy SMF of galaxies in the two CANDELS fields divided into galaxies with high and low Sérsic index and asymmetry. In Section 4 we interpret our results, and Section 5 summarizes our findings. Throughout we assume $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. AB magnitudes and a Chabrier initial mass function (IMF) are used unless otherwise indicated.

2 DATA AND SURVEYS

For this work a sample of galaxies at redshifts $0.3 < z < 3.0$ from the UDS data release 8 (DR8) data set, as well as the CANDELS-UDS and CANDELS GOODS-S data sets is selected. Using the combination of these two data sets we robustly probe the evolution of both the most massive galaxies over a wide area using the UDS, and fainter galaxies over a smaller area using the deep CANDELS UDS and GOODS-S data. We can take advantage of the different strengths of the two data sets, such as the wide area of the UDS which allows us to measure galaxy environment, and the high-resolution CANDELS imaging which allows us to explore galaxy structure. Hereafter, we will refer to the UDS, CANDELS UDS and CANDELS GOODS-S data sets as the UDS, C-UDS and GOODS-S, respectively.

2.1 Photometry

2.1.1 The UDS

The UDS DR8 data reaches 5σ , 2 arcsec aperture depths of $J = 24.9$, $H = 24.2$ and $K = 24.6$ and covers a total of 0.88 deg^2 . This survey

contains over 100 000 galaxies with reliable redshifts, stellar masses and rest-frame colours. The area of the UDS allows us to probe different galaxy environments. For further information on the UDS see Almaini et al. (in preparation).

In this study, spectral energy distribution (SED) fitting was used to compute photometric redshifts, stellar masses and rest-frame colours. To perform this analysis robustly it is vital to have a large multiwavelength data set. The UDS benefits from additional wavelength coverage from various other surveys: optical B, V, R, i, z -band data from the *Subaru/XMM-Newton* Deep Survey (SXDS; Furu-sawa et al. 2008) and U -band data from the CFHT (Foucaud et al., in preparation), 3.6 and 4.5 μm (Infrared Array Camera (IRAC) channels 1 and 2) data from the UDS Spitzer Legacy Programme (SpUDS; PI: Dunlop). The 24 μm data from SpUDS (limited to $300 \mu\text{Jy}$; 15σ) is also used in this work for test purposes but not included in the SED fitting (see Section 2.3.2). For further discussion of the data used in the UDS see Almaini et al. (2014) and Hartley et al. (2013).

2.1.2 CANDELS UDS

CANDELS is a Multi Cycle Treasury Programme which images objects with both the Wide Field Camera 3 (WFC3) and the Advanced Camera for Surveys (ACS). In total, CANDELS consists of 902 orbits of the *Hubble Space Telescope* (HST) and covers 800 arcmin^2 . This area is made up of five different fields: GOODS-N, GOODS-S, EGS, COSMOS and UDS. CANDELS is divided into two parts CANDELS/Deep which images GOODS-N and GOODS-S to a 5σ point source depth of $H = 27.7 \text{ mag}$, and CANDELS/Wide which images all fields to a 5σ depth of $H = 26.3$ in a 1 arcsec aperture.

For this work, we use the CANDELS data that cover a part of the UDS field and the GOODS-S field, both of which have a pixel scale of $0.06 \text{ arcsec pixel}^{-1}$. The areas of the C-UDS and GOODS-S are approximately 0.06 and 0.05 deg^2 . For further details on the CANDELS data see Grogin et al. (2011) and Koekemoer et al. (2011). This study utilizes the UDS and GOODS-S photometry presented in Galametz et al. (2013) and Guo et al. (2013), respectively.

As C-UDS is a subset of the UDS field it also benefits from the same wealth of ancillary data as the UDS data set (Section 2.1.1). However, in addition to the U -band CFHT data, B, V, R, i, z -band SXDS data and J, H and K -band data from UKIDSS, the C-UDS data set also includes additional photometry. This includes $F606W$ and $F814W$ data from the ACS, H_{160} and J_{125} -band HST WFC3 data from CANDELS, Y and K_s bands taken as part of the HAWK-I UDS and GOODS-S survey (HUGS; VLT large programme ID 186.A-0898, PI: Fontana; Fontana et al. 2014). For the C-UDS, the 3.6 and 4.5 μm data are taken as part of the Spitzer Extended Deep Survey (SEDS; PI: Fazio; Ashby et al. 2013). SEDS is deeper than SpUDS, which is used in the UDS data set, but is only available over a 0.17 deg^2 region. Therefore, SEDS is a more appropriate choice for the much smaller C-UDS area. For a detailed discussion of the C-UDS field and the C-UDS photometry used in this work see Galametz et al. (2013).

2.1.3 CANDELS GOODS-S

The GOODS-S photometry consists of 17 bands from both ground- and space-based telescopes. This includes two U bands, one taken with the MOSAIC II imager on the Cerro Tololo Inter-American Observatory (CTIO) Blanco telescope and one with the VISIBLE MultiObject Spectrograph (VIMOS) instrument on the VLT. There are also ACS $F435W, F606W, F775W, F814W, F850LP$ data, as

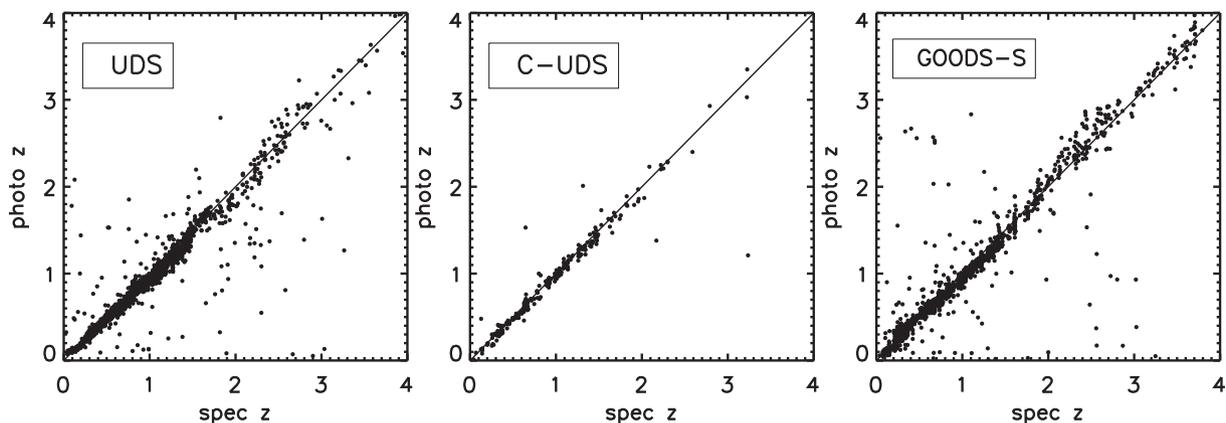

Figure 1. Left-hand panel: spectroscopic redshifts versus photometric redshifts for 2146 galaxies in the UDS with highest confidence spec- z after excluding AGN. Middle panel: spectroscopic redshifts versus photometric redshifts for 285 galaxies in the C-UDS which have spectroscopic redshifts from UDS z . Right-hand panel: spectroscopic redshifts versus photometric redshifts for 1840 galaxies in the GOODS-S which have spectroscopic redshifts as described in Dahlen et al. (2013).

well as the WFC3 $F098W$, $F105W$, J_{125} and H_{160} -band data. There are two sets of K -band photometry available in the GOODS-S. The first was taken using the Infrared Spectrometer And Array Camera (ISAAC) instrument on the VLT and the second was taken as part of the HUGS programme using HAWK-I on the VLT. Finally, the photometry catalogue includes all four IRAC bands from SEDS and incorporates the pre-existing cryogenic observations from the GOODS Spitzer Legacy project (PI: Dickinson). For full details of the GOODS-S data see Guo et al. (2013), and references therein.

2.1.4 Homogenization

It is important to consider how the data sets used in this study are homogenized. Correct homogenization is crucial when combining data sets to ensure that total magnitudes and colours are in agreement between different data sets.

In the two CANDELS fields the software package `TFIT` (Laidler et al. 2007) is used to derive all the photometry for non-*HST* data products. This package uses prior information on the position and morphology of any given object in a high-resolution image to obtain the flux of that object in a lower resolution image. Part of the `TFIT` process takes into account varying point spread functions (PSFs) and hence one of `TFIT`'s advantages is that it automatically provides correct colours. If the UDS corrections were applied to the two IRAC channels as well as the U -band data to obtain the correct colours. None of the other bands were corrected as the PSF sizes in the remaining bands are very similar (0.77–0.84 arcsec; Simpson et al. 2012). In short, the corrections were computed by using the K band (for IRAC) or B band (for the U band) to estimate the flux lost due to the larger PSFs. For the U band the corrections were only typically of 1 per cent, whereas for the two IRAC bands the correction could be between 26 and 30 per cent.

In all of the fields used in this work total fluxes are estimated using the `SEXTRACTOR` parameter `FLUX_AUTO`. For the two CANDELS fields all *HST* bands are converted to total fluxes using the ratio of `FLUX_AUTO/FLUX_ISO`. This was done prior to the `TFIT` process, and hence the resulting photometry is total. In the UDS the conversion to total is applied to the stellar masses and rest-frame magnitudes after photometry fitting using the ratio of `FLUX_AUTO/FLUX_APER`. Good agreement is found between the total K -band fluxes measured in the UDS and C-UDS. The

median difference is $0.07 \mu\text{Jy}$ which corresponds to a median stellar mass difference of 0.03 dex.

2.2 Photometric redshifts

2.2.1 The UDS photometric redshifts

Photometric redshifts for the UDS sample were computed by Hartley et al. (2013). They were determined via fitting template SEDs to the photometric data points described in Section 2.1.1 using the `EAZY` code (Brammer, van Dokkum & Coppi 2008). The photometry was fit to the linear combinations of the six default `EAZY` templates, and an additional template which is the bluest `EAZY` template with a small amount of Small Magellanic Cloud-like extinction added ($A_v = 0.1$). The redshifts were from maximum likelihood analysis. For full details of the fitting procedure and resulting photometric redshifts see Hartley et al. (2013).

A comparison of the photometric redshifts used in this work to spectroscopic redshifts that are available in the UDS was carried out in Hartley et al. (2013). Spectroscopic redshifts are from the UDS z , an European Southern Observatory large spectroscopic survey (ID: 180.A-0776) within the UDS. The spectroscopic redshifts within UDS z are for K -selected galaxies ($K_{AB} < 23.0$) which were chosen to be at redshifts of $z > 1$ and also include a low-redshift control sample. The UDS z spectroscopic redshifts are combined with spectroscopic redshifts from the literature (see Simpson et al. 2012, and references therein). From these two sources, and after exclusion of AGN, Hartley et al. (2013) used 2146 spectroscopic redshifts for comparison to photometric redshifts. Excluding catastrophic outliers ($\Delta z/(1+z) > 0.15$, ~ 3 per cent), the dispersion of $z_{\text{photo}} - z_{\text{spec}}$ is $\Delta z/(1+z) = 0.03$ for this data. The left-hand panel of Fig. 1 shows the spectroscopic redshifts versus the photometric redshifts for the 2146 galaxies used to calculate the quality of our photometric redshifts. Objects with spectroscopic redshifts are the brightest subset of galaxies and for fainter systems the dispersion will be larger. This is discussed further in Section 2.3 where a comparison between the UDS and C-UDS is made.

2.2.2 The CANDELS UDS and GOODS-S photometric redshifts

The C-UDS photometric redshifts were calculated using the same method as for the UDS sample described above. For the C-UDS, the

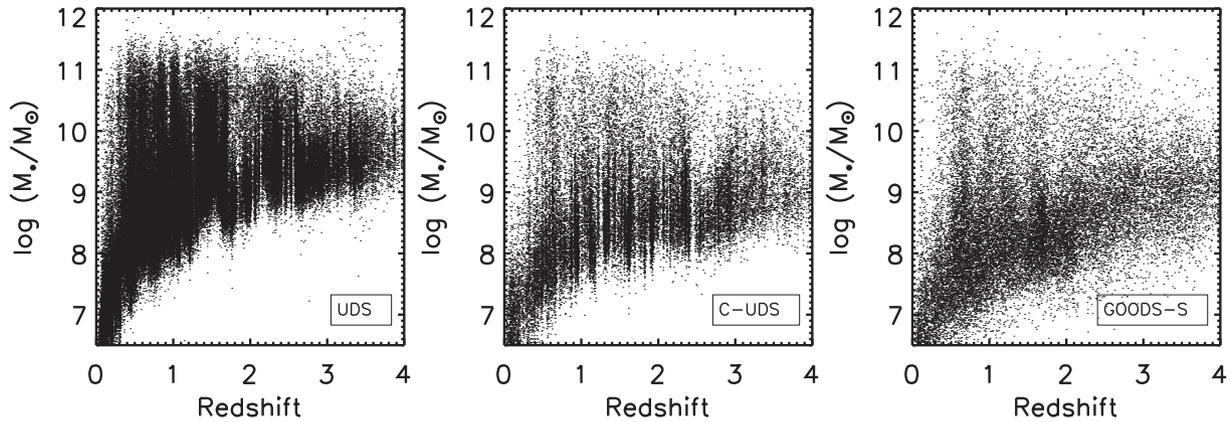

Figure 2. Left-hand panel: the stellar masses as a function of redshift for all galaxies in the UDS. Middle panel: the stellar masses as a function of redshift for all galaxies in the C-UDS. Right-hand panel: the stellar mass as a function of redshift for all galaxies in GOODS-S.

SED templates are fit to the photometry described in Section 2.1.2 and the best-fitting redshift is used. The middle panel of Fig. 1 shows the spectroscopic redshifts versus the photometric redshifts for the 285 CANDELS galaxies which have spectroscopic redshifts (see Galametz et al. 2013 for details of these spectroscopic redshifts). The dispersion of $z_{\text{photo}} - z_{\text{spec}}$ is $\Delta z/(1+z) = 0.026$ for our C-UDS photometric redshifts (after removal of the 2 per cent of catastrophic outliers), although it is noted that we have only a small sample of spectroscopic redshifts to compare to within the C-UDS region.

The photometry used to compute the GOODS-S photometric redshifts is described in Section 2.1.3 and the method, which uses the probability weighted redshift, is described in detail in Duncan et al. (2014). Fig. 1 shows a spectroscopic versus photometric redshift comparison for 1840 of the GOODS-S galaxies which have spectroscopic redshifts. These spectroscopic redshifts are from a compilation of data from GOODS-S which is described in full in Dahlen et al. (2013), and references therein. We find a dispersion of $z_{\text{photo}} - z_{\text{spec}}$ is $\Delta z/(1+z) = 0.036$ when catastrophic outliers (4 per cent) are removed as before.

Dahlen et al. (2013) looked in detail at the photometric redshift analysis of the CANDELS fields and discussed the merits of combining different photometric redshifts for individual objects from multiple techniques to produce the best final redshift. For both the C-UDS and GOODS-S, the scatter and catastrophic outlier fractions are comparable to those produced with the optimized CANDELS photometric redshifts. Therefore we are confident that our photometric redshifts are of the highest possible quality.

2.3 Stellar masses and rest-frame magnitude

The method used to compute the stellar masses and rest-frame magnitudes used in this work is described in detail in Mortlock et al. (2013), Hartley et al. (2013) and Lani et al. (2013). In brief, a large grid of synthetic SEDs was constructed from the stellar population models of Bruzual & Charlot (2003, hereafter BC03), assuming a Chabrier IMF (Chabrier 2003). The reddening law of Calzetti et al. (2000) was used to include dust in the templates. The SF history was characterized by an exponentially declining model with various ages, metallicities and dust extinctions. These models were parametrized by an age of the onset of SF, and by an e-folding time such that

$$\text{SFR}(t) \sim \text{SFR}_0 \times e^{-t/\tau}, \quad (1)$$

where the values of τ ranged between 0.01 and 10.0 Gyr, while the age of the onset of SF ranged from 0.001 to 13.7 Gyr. The

metallicity ranged from 0.0001 to 0.05 (BC03), and the dust content was parametrized by τ_v , the effective V-band optical depth for which we used values $\tau_v = 0, 0.4, 0.8, 1.0, 1.33, 1.66, 2, 2.5$ and 5.0. Other SF histories are not investigated in this work as studies have shown that stellar mass calculations are generally robust to changes in SF history within our redshift range and for the stellar masses probed in this work (e.g. Ownsworth et al. 2012; Pforr, Maraston & Tonini 2012; Reddy et al. 2012; Ilbert et al. 2013).

Each template was scaled to the apparent magnitude of the detection band magnitude of the galaxy. For the UDS we used the K-band magnitude, and for the C-UDS and GOODS-S the H_{160} band was used. The χ^2 was then computed for each template and from the best-fitting template best-fitting stellar masses and best-fitting rest-frame magnitudes were obtained. A modal mass value was also calculated by binning the stellar masses of the 10 per cent of templates with the lowest χ^2 in bins of 0.05 dex. The mode of the stellar mass corresponds to the stellar mass bin with the largest number of templates. In this analysis we use the mode of the stellar masses and the best-fitting rest-frame magnitudes as discussed in Mortlock et al. (2013).

Uncertainties on the stellar masses and rest-frame colours were computed from a Monte Carlo analysis. For each galaxy, simulated photometry was created by randomly choosing a point on a Gaussian curve whose standard deviation is the measured uncertainty on the photometry. This was done for each input band, and then the stellar mass and rest-frame colours from the simulated photometry were computed. This was then repeated 500 times and the uncertainty was taken as the standard deviation of the 500 Monte Carlo realizations. Furthermore, uncertainties due to the photometric redshift measurements were computed using the same method. The uncertainty from the photometry and the uncertainty from the photometric redshift were summed in quadrature and this was taken as the final uncertainty on the stellar masses. The stellar masses as a function of redshift are shown in Fig. 2 for all galaxies in the UDS (left-hand panel), the C-UDS (middle panel) and GOODS-S (right-hand panel). The cut off in stellar mass in this figure highlights the difference in survey depths.

Several studies have shown that the high-redshift systems can exhibit SEDs which are better fitted with the inclusion of nebular emission lines, and that these fits which include nebular emission result in lower stellar masses and ages (Zackrisson, Bergvall & Leitert 2008; Schaerer & de Barros 2009; Ono et al. 2010; Raiter, Fosbury & Teimoorinia 2010; Schaerer & de Barros 2010; McLure et al. 2011, Curtis-Lake et al. 2013; Duncan et al. 2014). These

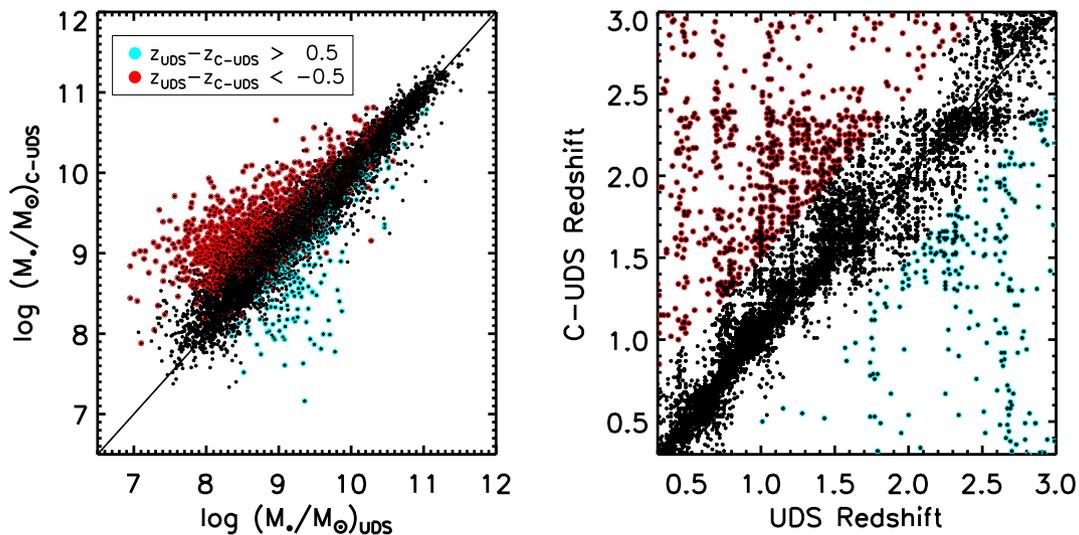

Figure 3. Left-hand panel: the stellar masses from the UDS field versus the stellar masses of the C-UDS field (black points). Right-hand panel: the photometric redshifts for the UDS field versus the C-UDS field. Overplotted in red and blue are galaxies with large differences in photometric redshifts measured from the two different sets of photometry (~ 11 per cent of galaxies with $0.3 < z < 3$).

studies focus on redshift ranges much higher than what is explored in this work, however it is important to investigate any potential impacts this may have on our results. As the impact from nebular emission is expected to be on objects with lower stellar masses and younger ages we test the GOODS-S sample as this provides the strongest constraint on the low-mass end of the galaxy SMF.

We recompute the stellar masses of the GOODS-S sample including nebular emission in the SED templates (see Duncan et al. 2014 for discussion of the prescription for including nebular emission). For any given stellar mass bin, at any given redshift, the mean difference between the stellar mass with and without nebular emission is always a factor of 10 to 100 smaller than the mean uncertainty on the stellar masses in that mass and redshift bin. The only exceptions to this are in the redshift range $2.0 < z < 2.5$ where we find mean differences of ~ 0.2 (i.e. of the order of the uncertainties on the stellar masses) in the stellar mass range $M_* = 10^{7.5} - 10^{8.5} M_\odot$. However, due to our completeness limits, galaxies of these stellar masses are not included in our SMFs in this redshift range. It is also possible that some low-mass, low metallicity objects have such large emission lines that their photometry is boosted and they are therefore fitted as high-mass systems. We compute the difference between the stellar masses with and without nebular emission and find that no galaxy changes mass by more than ~ 1.5 dex. Furthermore, the objects with this large difference are found only at the low-mass end of the galaxy SMF ($M_* \sim 10^8 M_\odot$). These objects will not be contaminating the high-mass end of the galaxy SMF where the number density can be changed greatly by the inclusion/loss of just one object. Therefore we conclude that nebular emission lines do not impact our findings. These findings are in agreement with Santini et al. (submitted) who performed a comparison of galaxy properties derived from SED fits to a variety of model, with varying parameters, for the same GOODS-S galaxies which are used in this comparison. In terms of differences due to nebular emission, they find that only a subsample of young galaxies are affected and that the impact is harshest in the redshift range $2.2 < z < 2.4$ (as well as in several outside the range of this work).

2.3.1 Redshift and stellar mass differences

The left-hand panel of Fig. 3 shows the comparison between the UDS stellar masses and the C-UDS stellar masses for our sample where the two field overlap. Overplotted in blue are galaxies for which $z_{\text{UDS}} - z_{\text{C-UDS}} > 0.5$, where $z_{\text{UDS}} - z_{\text{C-UDS}}$ is the difference in the redshift computed from the UDS photometry and the redshift computed from the C-UDS photometry. This is found to be ~ 3 per cent of the galaxies in the redshift range $0.3 < z < 3.0$. The red symbols are galaxies for which $z_{\text{UDS}} - z_{\text{C-UDS}} < -0.5$ (~ 8 per cent of the full data set in the redshift range $0.3 < z < 3.0$) and hence any major differences in stellar masses are a result of disagreements in the photometric redshifts. This can be seen in the right-hand panel of Fig. 3, which shows the comparison between the UDS and C-UDS photometric redshifts.

Although superficially the spread appears large, only 11 per cent of the sample is discrepant by more than 0.5 in redshift and these are the galaxies which are close to the detection limit in the UDS. Therefore, (a) a change in the photometric redshifts of the faintest objects is not necessarily a surprise due to the improved photometry for the deeper data and (b) there are many galaxies at the low-mass end and hence a small change in number will have less impact. Furthermore, the different depths of mid-IR data used for the two data sets (see Section 2.1.2) will impact our photometric quantities. Despite the apparently large scatter it is noted that the median offset in each redshift bin is acceptable. The offset ranged from -0.03 in the lowest redshift bin to 0.18 in the highest redshift bin. The median offset in stellar mass in the lowest redshift bin is -0.02 , which increases to 0.1 in the highest redshift bin. Hence, on average, we are finding good agreement between these two surveys.

It is important to consider how these problem galaxies (galaxies for which the difference in UDS and C-UDS redshift is more than 0.5) impact the galaxy SMF as a function of stellar mass. As previously mentioned many of the problem galaxies are near the magnitude limit of the UDS and include shallower IRAC data in the UDS. As a test the assumption is made that the C-UDS redshifts and masses are closer to the true redshifts and stellar masses for

the specific problem galaxies. We stress that there is no reason to assume this is the case for brighter galaxies and also that there are clearly scenarios in which the properties derived from the C-UDS are not the best answer (e.g. some image problem resulting in bad photometry).

In each redshift bin, as defined by the C-UDS redshifts, there are a given number of galaxies which could have problem redshifts (difference in UDS and C-UDS redshift is greater than 0.5) and hence masses in the UDS. However, as many of these galaxies are faint they are below the UDS stellar mass limit and hence do not contribute to the SMF. Furthermore many of these objects are below the UDS stellar mass limit according to both their UDS and C-UDS stellar masses, further evidence that they should not contribute to the SMF. Taking this into account we find that in our six redshift bins ($z \sim 0.4, 0.75, 1.25, 1.75, 2.25, 2.75$) the percentages of problem galaxies are 0.27, 0.31, 4.13, 10.77, 17.15 and 5.0 per cent, respectively. For most of the redshift bins this percentage is encouragingly small. Further to this, when comparing the UDS and C-UDS properties of these systems at redshifts of $z > 1$ there is no trend such that a specific redshift or mass always moves to another redshift or mass bin. At redshift of $z < 1$ there is a tendency for the redshifts and stellar masses of the problem objects to be higher in the UDS, however the contamination percentage is so low that this is unlikely to affect the shape of the galaxy SMF.

Finally, there are two specific problem regions to consider further. The first is the redshift range $1.5 < z < 2.5$ where the contamination percentage is high. The second is the high-mass end of the galaxy SMF where the introduction or removal of a small number of objects can make a large difference. In the redshift range $1.5 < z < 2.5$ it is a worry that the high percentage of problem objects may affect the shape of the galaxy SMF. However, if this was the case there would be a difference in the UDS and C-UDS number densities which would be obvious by inspection. No such difference is found except for a small possible discrepancy in normalization between the two fields. This may be explained by galaxies which have been scattered out of the UDS number densities into other redshift and stellar mass bins.

At the high-mass end of the galaxy SMF there is only 1 galaxy within the sample of problem galaxies which is massive ($M_* > 10^{11} M_\odot$) in the UDS (in the redshift bin $2.5 < z < 2.0$) but not the C-UDS. As a simple test as to how much this potentially changes the high-mass end, it is assumed that there are 11 objects in this bin which are contaminated (as the UDS is ~ 11 times the area of the C-UDS). If this number is subtracted from the actual number of objects in that bin we find that the resulting number density is still within error of the previous result. We therefore argue this has no significant effect on our results at the high-mass end (for further discussion see Section 3.1.1). It is important to note that the fainter galaxies in the UDS, which are the drivers behind the large spread, will also have larger uncertainties on their photometric redshifts and stellar masses. As these uncertainties are accounted for in our analysis (see Section 3.1), the difference in photometric redshifts and stellar masses will be represented in the uncertainties on any quantity computed in this work.

2.3.2 UVJ selection

To divide our galaxies into red and blue (passive and star-forming) populations we used rest-frame *UVJ* colours as in Wuyts et al. (2007). Williams et al. (2009) applied this method to the UDS DR1 and found that galaxies can be divided robustly into red/blue

populations using the *UVJ* criteria up to redshifts of $z \sim 2$. Furthermore, Hartley et al. (2013) showed that this can be extended to redshifts of $z > 2$ using the greater number statistics of the UDS DR8. We therefore adopt the following criteria to divide our sample into red and blue systems. A galaxy is considered red, or passive, if

$$(U - V) > 1.3 \quad \text{and} \quad (V - J) < 1.6 \quad (2)$$

with the additional redshift-dependent criteria that

$$(U - V) > \begin{cases} 0.88 \times (V - J) + 0.69 & 0.3 < z < 0.5 \\ 0.88 \times (V - J) + 0.59 & 0.5 < z < 1.0 \\ 0.88 \times (V - J) + 0.49 & 1.0 < z < 2.5, \end{cases}$$

where $U - V$ and $V - J$ are the rest-frame colours computed from the magnitudes discussed in Section 2.3.

The *UVJ* criteria are often used to distinguish between passive and star-forming objects. However, dusty, star-forming galaxies will contaminate the passive region, and hence the selection is not perfect. Hartley et al. (2013) used an additional cut to remove star-forming objects from the passive sample, although they found that this had very little impact on their results. Our sample was tested for this by removing all galaxies with a $24 \mu\text{m}$ detection from the passive sample. In our redshift range, and for any given stellar mass bin, the change in number density is on average ~ 2 per cent (maximum change to a single stellar mass bin is ~ 15 per cent). It is noted that much of the $24 \mu\text{m}$ data are at redshifts of $z < 1$ but we can say that there is no evidence for contamination given the data available to us.

To fully understand the impact of contamination arising from the *UVJ* selection on our results we would ideally need to know how the contamination changes as a function of stellar mass and redshift. However, without a considerable amount of spectra this is difficult to test. Previous studies have looked at how SF rates correlate with position on the *UVJ* diagram. Brammer et al. (2011) showed that the *UVJ* selection criteria can clearly separate objects which are star forming or quiescent based on their UV+IR SF rates up to redshifts of $z = 3$ and down to stellar masses of $M_* \sim 10^{10} M_\odot$. Furthermore, Wuyts et al. (2007) showed that systems in the quiescent part of the *UVJ* diagram, with stellar masses down to $M_* \sim 10^9 M_\odot$, are consistent with being old passively evolving populations based on their properties from SED fitting.

There have been a handful of studies which spectroscopically demonstrate the reliability of the *UVJ* selection. For example, Williams et al. (2009) showed that a sample of 96 old, passively evolving galaxies, which are spectroscopically confirmed, lie on the correct place on the *UVJ* diagram. These objects have redshifts of $z < 2.5$ and *K*-band magnitudes brighter than $K < 22.4$. Whitaker et al. (2013) showed that the *UVJ* selection is very effective at selecting spectroscopically confirmed passive galaxies from the 3D-HST grism survey out to redshifts of $z \sim 2$ and most recently Belli et al. (2014) have used spectroscopic properties to show that galaxies which lie in the quiescent region of the *UVJ* diagram are genuinely quiescent (e.g. not contamination from dusty star-forming galaxies). This sample of galaxies is in the redshift range $1 < z < 1.6$ and has stellar masses of $M_* > 10^{10.7} M_\odot$.

It is important to note that the uncertainties on the number densities of red and blue objects include consideration of the scattering of objects around the *UVJ* diagram due to errors on the rest-frame magnitudes (e.g. due to uncertainties in the photometry). Therefore we believe the average contamination is represented in the results

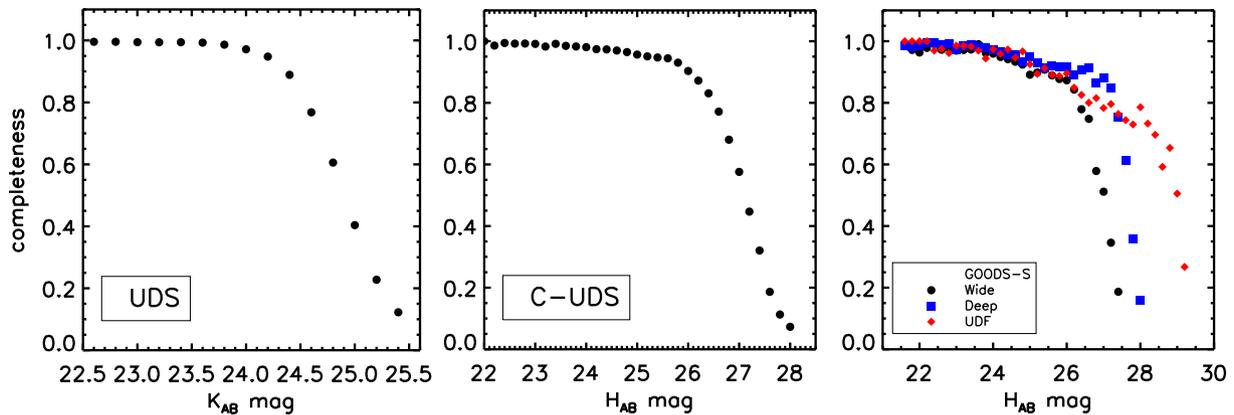

Figure 4. The left-hand, middle and right-hand panels are the completeness curves as a function of magnitude for the UDS (Almaini et al. 2014), the C-UDS, and the three regions in the CANDELS GOODS-S (Yan et al. 2012), respectively. In the right-hand panel, the black symbols are for the wide region of GOODS-S, the blue symbols are for the deep region and the ERS region, and the red symbols are for the HUDF.

presented for the blue and red SMFs. However we can perform a similar test, as in Section 2.3.1, where we consider the comparison between the UDS and C-UDS UVJ classifications. In this way we can explore how galaxies move around the UVJ diagram due to differences in these two data sets. For blue (or star-forming) systems in the C-UDS the percentage of objects which have a different UVJ classification in the UDS is not a strong function of mass or redshift. At $M_* > 10^{11} M_\odot$ the contamination percentage is zero at all redshifts. For stellar masses of $M_* < 10^{11} M_\odot$ down to the stellar mass limit of the UDS the percentage is generally of the order of a few to 10 per cent at all redshifts. However, there are some stellar mass bins where it can be as high as 18 per cent.

For the passive or red galaxies the change in classification does seem to be a function stellar mass such that it gets progressively worse for intermediate stellar masses. Considering objects with $M_* > 10^{11.5} M_\odot$ there is no shift, however when looking at objects with stellar masses of $10^{11} < M_* < 10^{11.5} M_\odot$ the change ranges from as little as 5 per cent to as much as 25 per cent in the different redshift bins. At stellar masses of $10^{10} < M_* < 10^{11} M_\odot$ the average change is ~ 20 per cent (however it ranges from zero change to as large as ~ 40 per cent in one stellar mass bin). For stellar mass bins of $M_* < 10^{10} M_\odot$ the average shift is again ~ 20 per cent however there is a smaller spread across the different redshift ranges (as low as zero and as high as ~ 30 per cent in one stellar mass bin.) Although there does seem to be a general trend of the contamination getting worse at higher redshift the trend is not smooth.

Some caution needs to be taken when considering these results (as with the results in Section 2.3.1). It is not necessarily true that the C-UDS gives us the ‘correct’ answer when compared with the UDS. There are other factors which need to be considered which could mean that for a given object the UDS photometry is more accurate (e.g. image quality at a given part of the detector or distance from the edge of the image). When considering galaxies which have a different UVJ classification in UDS to C-UDS at a given stellar mass, a given redshift, and a given colour small number statistics begin to impact these results. There are often only of the order of tens of objects which have different UVJ classifications between the two data sets and hence if the assumption that C-UDS is ‘correct’ is wrong for just a few then this can change the percentages reported here. It is worth noting that the similarity between the number densities for red and blue objects, in the UDS and the C-UDS, indicates that any potential contamination does not seem to have a large impact upon our results.

2.4 Completeness

As low stellar masses are probed at high redshift, number densities become incomplete as the faintest galaxies cannot be observed. Using the detection completeness as a function of magnitude (shown in Fig. 4) we corrected the number densities for the total galaxy SMFs. Fig. 4 shows the completeness for the three surveys used in this work. The horizontal axis of the left-hand panel is K band and the middle and right-hand panels are H band. For the galaxies used in this study the typical observed $H - K$ colours are ~ 0.5 . Here we describe briefly the methods for calculating the completeness functions.

UDS. The detection completeness for the UDS was computed by Almaini et al. (2014) by first creating a fake UDS background image by removing all the real sources and replacing them with background pixels. Next, for each magnitude of interest, real galaxies which are slightly brighter than the magnitude being tested were rescaled to the magnitude of interest. These artificially dimmed galaxies were then inserted into the fake background and `SEXTRACTOR` is run. The completeness is the fraction of correctly extracted sources.

C-UDS and GOODS-S. The C-UDS and GOODS-S completeness comes from catalogues of simulated galaxies. These artificial sources had been inserted into the C-UDS or GOODS-S background using the `IRAF` routine `MKOBJECTS`. In the C-UDS the fake galaxies had either exponential or de Vaucouleurs profiles, whereas in the GOODS-S simulated catalogue the sources had varying ellipticity. In both fields sources had a randomly assigned H_{160} -band magnitude, and a distribution of sizes. To compute the completeness fraction, simulated galaxies were randomly selected, in the H_{160} -band magnitude bin of interest, such that the distribution of sizes of the simulated galaxies matches that of real galaxies. The distribution of sizes of real galaxies for the C-UDS and GOODS-S was taken from van der Wel et al. (2012). The fraction of these artificial sources recovered by `SEXTRACTOR` was then calculated in each of our magnitude bins.

To correct our number counts each galaxy was weighted by $1/\text{completeness}$ according to the H_{160} -band magnitude of the galaxy. Given that the fake sources created for the UDS completeness were inserted into a sourceless background, these simulation do not take into account confusion. However, the CANDELS completeness simulations do take confusion into account and there is no difference in the galaxy SMFs produced from these two methods

of performing completeness corrections. In particular, a difference would be expected at the low-mass end and, as none is seen, we conclude that this difference in completeness calculation does not affect the results in this work.

The GOODS-S observations are covered by three different regimes of varying depth. To ensure that each galaxy makes use of the deepest possible near-IR photometry, the GOODS-S data products were taken from a ‘max depth’ image which varies in depth. The three regions are wide, deep [which includes the Early Release Science (ERS)] and the Hubble Ultra Deep Field (HUDF). To account for this, we computed three different completeness curves and weighted each galaxy depending on where it lies within GOODS-S.

Part of the C-UDS is shallower than the deepest region that the simulations used to compute the corrections are based on. Galametz et al. (2013) showed that the eastern third has a limiting magnitude of $H_{160} < 27.90$, whereas the remaining two thirds has a limiting magnitude of $27.90 < H_{160} < 28.26$. Therefore, some proportion of the galaxies will not be fully corrected and, if this was a large effect it would result in a faint end slope which is shallower than the true value. However, the shallow region of the field is less than one third of the total area and hence the number densities will be dominated by galaxies which are in the deepest part of the field, and therefore the variations in depth will not affect our results drastically. Furthermore, our results match well with results from the literature (see Section 3.1) which utilize samples which are complete to low stellar masses. This suggests our conclusions are not being affected by the C-UDS depth variations.

The completeness correction allows us to better constrain the low-mass end of the galaxy SMF. However, this correction needs to be applied carefully as overcorrection would lead to an artificially steepening of the low-mass slope. In this work the corrections applied to the lowest mass number densities are typically of the order of 10 per cent in all fields.

For the UDS we use the stellar mass completeness limits computed in Hartley et al. (2013) and for the C-UDS and GOODS-S we compute the stellar mass limit using the same method. In brief, we take a small redshift slice around the redshift of interest ($\Delta z = 0.1$) and take the faintest 20 per cent of galaxies in this slice. We then rescale the stellar masses of these galaxies to the stellar mass at the 5σ limit of the survey ($K = 24.3$ for the UDS and $H_{160} = 26.0$ for C-UDS). We take the 95th percentile of the scaled stellar mass distribution as our 95 per cent completeness limit. For a full discussion of this method see Pozzetti et al. (2010).

2.5 Environments

The environments used in this study are computed by Lani et al. (2013) and a detailed discussion on how they are measured can be found there. In brief, the environments are computed from counts in a physical aperture. In Lani et al. (2013) a cylinder, of projected radius 400 kpc and depth 1 Gyr, was constructed around the galaxy for which the density is measured. A depth of 1 Gyr is substantially greater than the 1σ measured uncertainty on the redshifts, and hence was large enough to minimize the exclusion of sources due to large photometric redshift uncertainties, while also being small enough to avoid diluting the number of galaxies in the cylinder.

The number count of real galaxies (N_g^{Aper}) was normalized to account for edges and holes within the UDS and the final equation for the density is

$$\rho_{\text{aperture}} = \frac{N_g^{\text{Aper}}}{N_{\text{Mask}}^{\text{Aper}}} \times \frac{N_{\text{Mask}}^{\text{Tot}}}{N_z}, \quad (3)$$

Table 1. The mean environment density ($\langle\rho\rangle$) and standard deviation of the environment density distribution (σ_ρ) in each redshift bin for systems above the stellar mass limit.

Redshift range	$\langle\rho\rangle$	σ_ρ
$0.3 < z < 0.5$	1.20	0.57
$0.5 < z < 1.0$	1.20	0.61
$1.0 < z < 1.5$	1.13	0.48
$1.5 < z < 2.0$	1.11	0.46
$2.5 < z < 3.0$	1.12	0.49
$2.5 < z < 3.0$	1.12	0.45

where $N_{\text{Mask}}^{\text{Aper}}$ is the number of pixels within the aperture which were not masked, $N_{\text{Mask}}^{\text{Tot}}$ is the total number of non-masked pixels in the UDS and N_z is the number of galaxies in the whole field which lie in the considered 1 Gyr depth.

To divide the systems used in this study into different environment bins, we adopted the same selection method as Lani et al. (2013). For each redshift bin, the mean and standard deviation of galaxies of galaxy environments was calculated for systems above the stellar mass limit. The values of these can be found in Table 1. Galaxies which live in high-density environments were defined as those which had a density greater than one standard deviation from the mean density. The galaxies considered to be in low densities were those which have densities of less than one standard deviation from the mean.

As photometric redshifts are used to measure environments in this study, which can have large errors associated with them, galaxies can be scattered in and out of their true density bin. This problem is particularly worrying in the highest density bin where there are fewer objects and any objects will be preferentially scattered to lower densities. Therefore, we caution against comparing redshift bins to investigate evolution due to redshift. However, in Lani et al. (2013) the environments used in this work were found to recover known trends such as the colour–density relation. Furthermore, the location of objects in the highest densities correlates to the positions of known clusters even for faint systems. What this means is that for a given high- or low-density bin the overall real density distribution will be skewed to the high and low end, respectively. Thanks to the excellent number statistics within the UDS this means that we can compare galaxies within a single redshift bin and infer in a statistical manner whether any differences in galaxy properties are correlated with our measure of environment.

2.6 Structural parameters

2.6.1 Sérsic index

We employ structural parameters from the C-UDS and GOODS-S to construct the galaxy SMF of different galaxy populations. We utilize the Sérsic indices measured by van der Wel et al. (2012) from the H_{160} C-UDS image using GALFIT (Peng et al. 2010a). GALFIT computes the best-fitting Sérsic model, the parameters of which are total magnitude, half-light radius, Sérsic index, axis ratio and position angle. van der Wel et al. (2012) estimated random uncertainties by comparing independent measures of the same parameters for the same object, in deeper and shallower imaging and reported that the Sérsic index can be measured to an accuracy of 10 per cent or better for galaxies brighter than $H_{160} \sim 24.5$.

Our number density estimates extend down to faint magnitudes, where the structural parameter measurements are the least robust. However at a redshift of $z = 3$ ($z = 1$) the average stellar mass of galaxies with a magnitude of $H_{160} \sim 24.5$ is $M_* \sim 10^{9.5} M_\odot$ ($M_* \sim 10^{8.8} M_\odot$). We can therefore still explore the structural parameters of galaxies at these stellar masses to an accuracy of 10 per cent, despite the difficulties involved with these galaxies being faint.

2.6.2 CAS parameters

The concentration, asymmetry and clumpiness (CAS) parameters provide information on the structure of a galaxy. Asymmetry is a measure of the presence of disturbed features in a galaxy. A high asymmetry value indicates a peculiar or merging system. An object with a high concentration parameter has a centrally concentrated light profile, such as a spheroidal system. The clumpiness parameter indicates how smooth the light profile of a galaxy is. For this work, we ran the CAS code on the H_{160} -band C-UDS and GOODS-S images. In this work the clumpiness parameter was not used as it is found to be the least robust at high redshift due to issues resolving small clumps in these systems with WFC3 (Conselice 2003). Furthermore, the concentration parameter was not used as part of this analysis therefore only a description of the asymmetry parameter is included below. For a full description of the CAS code see Conselice (2003).

The asymmetry parameter was found by first placing a 3×3 grid over a galaxy. Then a 180° rotated image of a galaxy was subtracted from the original image. A background subtraction was included. The equation for this is as follows:

$$A = \min \left(\frac{\sum |I_0 - I_{180}|}{\sum I_0} \right) - \min \left(\frac{\sum |B_0 - B_{180}|}{\sum I_0} \right), \quad (4)$$

where I_0 is the original image pixels and I_{180} is the image after the 180° rotation. B_0 and B_{180} are the values used for the background subtraction. In this equation, the minimum refers to the minimum of the different regions of the grid. The minimum is found by changing the centre around in a 3×3 grid, so that the asymmetry is calculated nine times at each position. If the minimum of the nine is the central one then nothing further is done and that value is taken as the asymmetry. If this is not the case it moves the centre to the minimum position and recomputes the asymmetry in the 3×3 grid and continues to do so until the minimum is at the centre.

Uncertainties on the asymmetry are the standard deviation of the background subtraction used in CAS along with counting uncertainties from the galaxy itself. For a detailed discussion of how the CAS parameters are computed, including centring, measurement of radii and background subtraction see Conselice, Bershadsky & Jangren (2000) and Conselice (2003).

One difference between how CAS parameters have been calculated previously and how we calculated them in this work is the use of median asymmetries. For each galaxy, the asymmetry value is calculated four times, each time using a different area of sky for the background subtraction. We then took a median value as the final parameter. By calculating these structural parameters this way, we were less affected by areas of sky which did not well represent the background value of the image, for example, an area of bad pixels.

Despite the high-resolution data used to obtain the CAS parameters, there are still redshift-dependent resolution issues which need to be considered when measuring structural parameters. For example, if asymmetric structures such as clumps or spiral arms are being washed out this will cause the asymmetry values to be too low. The

asymmetry values were tested by artificially redshifting galaxies in the local Universe to redshifts of $z = 1.25, 1.75, 2.25,$ and 2.75 , and then remeasuring their CAS parameters as a function of redshift. As we moved to higher redshifts the asymmetry value systematically decreased. A correction was therefore applied based to these simulations of $\delta A = 0.02, 0.04, 0.06,$ and 0.08 at redshifts $z = 1.25, 1.75, 2.25$ and 2.75 , respectively. The method to artificially redshift these galaxies is described in full in Conselice (2003) and Mortlock et al. (2013).

3 RESULTS

3.1 The total galaxy stellar mass function

The galaxy SMF is a useful tool for investigating the build-up of stellar mass, and understanding the shape of the galaxy SMF is an important question in astronomy. Many studies have emphasized the importance of understanding the low-mass slope which gives us information on the faintest galaxies which are also the most abundant. This slope, and how it evolves with redshift, is difficult to determine robustly due to problems associated with observing faint galaxies. In this paper we use the deep data from C-UDS and GOODS-S to fit the SMF to stellar masses as low as $M_* = 10^9 M_\odot$ at redshifts of $z = 3$.

The UDS benefits from having deep near-IR data over a very large spatial area, and hence we can construct the galaxy SMF with excellent number statistics. This data set is ideal for constraining the number densities of rarer, massive galaxies, which would be difficult with only the small area of the C-UDS and GOODS-S. The combination of the three data sets used in this work allows us to robustly compute the number densities of galaxies over ~ 5 dex in stellar mass at redshifts of $z \sim 1.25$, and ~ 2 dex in stellar mass at redshifts of ~ 2.75 .

Fig. 5 shows the total galaxy SMFs for the combined UDS, C-UDS and GOODS-S data sets. The galaxy number counts were corrected for incompleteness as described in Section 2.4. To compute the uncertainties on the number densities we performed a Monte Carlo analysis. Each galaxy's stellar mass and redshift were varied along a Gaussian distribution with standard deviation equal to the 1σ measured uncertainty of the stellar masses and redshifts (see Section 2.3). The analysis was repeated on 100 simulated redshifts and stellar masses to obtain simulated number counts. The standard deviation of these values represents the uncertainty due to measurement error. The Poisson uncertainty for each of our number counts was computed and added in quadrature to the uncertainty from our simulations. Finally, uncertainties from cosmic variance were calculated from the GETCV code (Moster et al. 2011). This code computes a fractional uncertainty due to cosmic variance as a function of both redshift and stellar mass. These were also added in quadrature to our Monte Carlo uncertainties and Poisson uncertainty and this value was taken as the final uncertainty on the number densities.

To give a feel for the contribution to the uncertainty from each source, we take the $M_* \sim 10^{10.5} M_\odot$ stellar mass bin at redshifts of $z \sim 0.4$ and 1.25 . In the UDS, the Poisson error always contributes the least at both redshifts (~ 10 per cent). There is a small increase in the contribution of uncertainties from SED fitting from the redshift $z \sim 0.4$ to the $z \sim 1.25$ test bins (from 40 to 50 per cent). In the two CANDELS fields the lowest contribution to the uncertainty is from the SED fitting, and cosmic variance has a much larger impact, particularly in the highest of the two redshift test bins (~ 55 per cent).

In this study the number densities were computed as the number of galaxies in a given stellar mass bin normalized by the volume

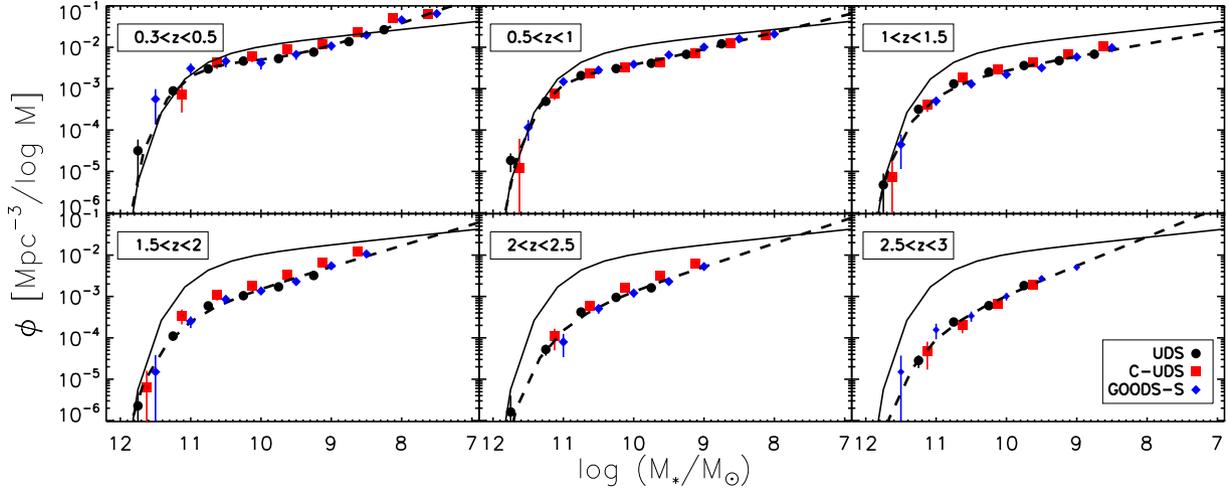

Figure 5. The total galaxy SMF for the combined fields. The black circles are the number densities for the UDS field, the red squares are the number densities for the C-UDS, and the blue diamonds are the number densities for the GOODS-S. The black dashed curves are the Schechter function fits to the combined data. In the redshift range $0.3 < z < 1$ the fits are double Schechter fits, whereas at redshifts of $z > 1$ the fits are single Schechter fits. The solid black curve is the local galaxy SMF from Cole et al. (2001) converted to a Chabrier IMF.

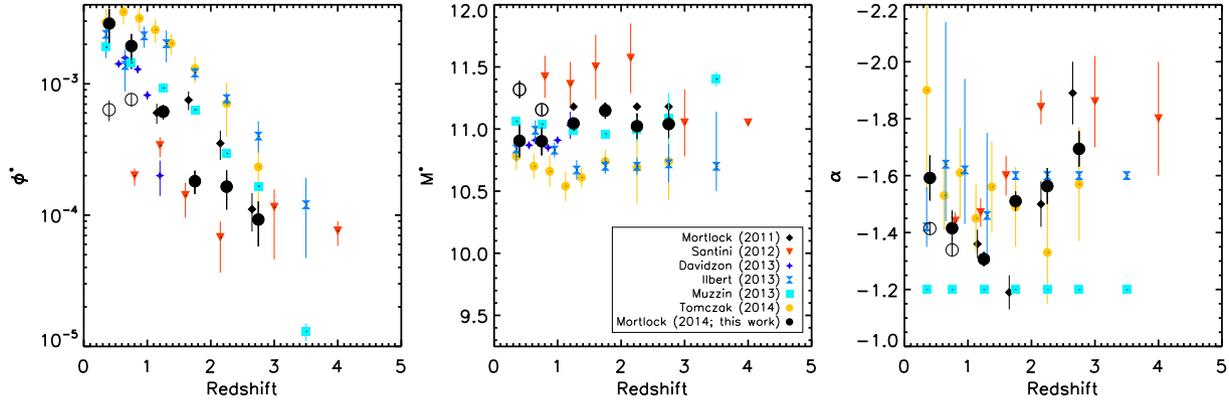

Figure 6. The Schechter function parameters of the fits shown in Fig. 5 (black filled circles). The black empty circles are from the single Schechter fits to the total galaxy SMF (not plotted in Fig. 5 but shown here for comparison). The black filled diamonds are the results from Mortlock et al. (2011), the blue filled squares are the results from Muzzin et al. (2013), the yellow filled circles are the results from Tomczak et al. (2014), the red filled triangles are the results from Santini et al. (2012), the blue filled bow ties are the results from Ilbert et al. (2013), and the blue filled stars are the results from Davidzon et al. (2013). Where necessary, we converted the literature values of M^* to a Chabrier IMF.

in a given redshift bin. For each of our surveys, separate number densities were computed using the volume of each individual survey. The three surveys were combined in such a way that our number densities are a smooth function of stellar mass (i.e. the mass bins used in the fitting are offset by 0.25 dex between each survey). The combination of the three fields was then fit by creating an array of all the computed number densities in order of the centre of the stellar mass bin. The combined data sets, in the redshift range $1 < z < 3$ were fit, using a least-squares fit, with a Schechter function (Schechter 1976) of the form:

$$\phi(M) = \phi^* \cdot \ln(10) \cdot [10^{(M-M^*)}]^{(1+\alpha)} \cdot \exp[-10^{(M-M^*)}], \quad (5)$$

where ϕ^* is the normalization of the Schechter function, M^* is the turnover mass in units of dex, α is the slope of the low-mass end of the Schechter function and M is the stellar mass in units of dex. However, in the redshift range $0.3 < z < 1$ it is clear by inspection that the data are better described by a double Schechter function.

The form of the double Schechter function is

$$\phi(M) = \ln(10) \cdot \exp[-10^{(M-M^*)}] \cdot 10^{(M-M^*)} \cdot [\phi_1^* \cdot 10^{(M-M^*)\alpha_1} + \phi_2^* \cdot 10^{(M-M^*)\alpha_2}], \quad (6)$$

where M is stellar mass in units of dex, M^* is the turnover mass in dex, ϕ_1 and ϕ_2 are the normalizations of the two Schechter components and α_1 and α_2 are the slopes of the two Schechter components. The reduced χ^2 of a single Schechter fit compared to a double is 2.95 and 1.91 in the redshift range $0.3 < z < 0.5$, and 1.94 and 1.59 in the $0.5 < z < 1.0$ redshift bin.

Fig. 6 shows the Schechter parameters for the fits to the total SMFs. The Schechter function parameters for the fitting are also in Tables 2 and 3. An overall increase of ϕ^* is found from low to high redshift, a steepening of α from low to high redshift, and little evolution of M^* across our redshift range.

Ilbert et al. (2013) and Tomczak et al. (2014) fitted their galaxy SMFs with a double Schechter function and hence for ϕ^* we plot the

Table 2. The single Schechter parameters for the total galaxy SMF. These parameters are plotted in Fig. 6.

Redshift range	M^*	$\log \phi_*$	α
$0.3 < z < 0.5$	10.90 ± 0.13	-2.54 ± 0.13	-1.59 ± 0.08
$0.5 < z < 1.0$	10.90 ± 0.11	-2.71 ± 0.10	-1.42 ± 0.06
$1.0 < z < 1.5$	11.04 ± 0.04	-3.21 ± 0.06	-1.31 ± 0.03
$2.0 < z < 2.5$	11.15 ± 0.06	-3.74 ± 0.09	-1.51 ± 0.03
$2.0 < z < 2.5$	11.02 ± 0.10	-3.78 ± 0.14	-1.56 ± 0.06
$2.5 < z < 3.0$	11.04 ± 0.11	-4.03 ± 0.16	-1.69 ± 0.06

sum of the normalizations of the two components of their Schechter functions. Furthermore, for α , we plot the slope of the low-mass component of their double Schechter functions as this is comparable to the low-mass slope of a single Schechter function. Muzzin et al. (2013) fitted with both a double and single Schechter function. Here we plot their results for a single Schechter function for comparison. We discuss the comparisons with other studies in Section 4.1.1.

3.1.1 Eddington bias

When computing the galaxy SMF it is important to consider the effect that the redshift and stellar mass uncertainties have on the shape of the galaxy SMF. The uncertainties in redshift and stellar mass will scatter objects between stellar mass bins. Due to the exponential decline at the high-mass end of the galaxy SMF there are fewer objects there. Therefore if an object scatters in or out of a high stellar mass bin this will have a larger effect on the number density. This is known as Eddington bias (Eddington 1913) and will have the greatest impact on the parameter M^* .

There have been several previous studies which have explored how Eddington bias changes the shape of the galaxy SMF. Caputi et al. (2011) found that in the redshift range $3 < z < 4.25$ the M^* parameter is large and that Eddington bias does not have a significant effect. However, at higher redshift ($4.25 < z < 5$) the high-mass end is flattened compared to lower redshifts and this can change the number density of massive galaxies by as much as 0.13 dex. Ilbert et al. (2013) explore Eddington bias in a similar redshift range to what is considered in this work. By de-convolving their computed number densities by the stellar mass errors they show that across the redshift range $0.8 < z < 4$ only the high-mass turnover is affected and that this change is always less than 0.1 dex.

To understand the effects of Eddington bias on the galaxy SMFs in this study we artificially inflated our stellar masses by adding a number taken from a Gaussian distribution with a full width at half-maximum equal to the 1σ uncertainty of a given object. The number densities are then recalculated based on these masses and then refit the resulting galaxy SMFs. This was repeated 500 times. By forcing the stellar masses to be larger based on their measured uncertainties a worst case scenario is being imposed in which galaxies are forced into higher stellar mass bins. The high-mass turnover M^* can increase by as much as to 0.6 dex, although on average is of the order of 0.1 to 0.2 dex.

The uncertainties on the stellar masses used in this study take into account both the uncertainties on the photometry and on the photometric redshifts. Therefore the stellar mass uncertainties incorporate the differences between the individual data sets used and hence our test of Eddington bias takes into account the varying quality of photometry, redshifts and stellar masses. By also testing variations in our fits when inflating the stellar masses we are taking a further step and exploring the highest impact on our results. However, to study the true impact of Eddington bias it is necessary to know the intrinsic galaxy SMF which results in the observed galaxy SMF after all stages of data reduction are taken into account. This requires detailed simulations which we defer to a future paper.

3.2 The galaxy stellar mass function of blue and red systems

With the combined data set used in this study, we explore the galaxy SMF with respect to colour down to low stellar masses, and with excellent number statistics. The galaxy sample was divided into red and blue galaxies using the *UVJ* selection described in Section 2.3.2 and number densities were computed in redshift bins between $0.3 < z < 3$, for the UDS, the C-UDS and the GOODS-S. The colour divided galaxy SMFs were completeness corrected as discussed in Section 2.4.

The resulting colour divided galaxy SMFs can be found in Fig. 7. All blue SMFs were fitted with a single Schechter functions and the red SMFs in the redshift range $1 < z < 3$ were also fitted with a single Schechter function. In the redshift range $0.3 < z < 1$ the red SMFs were fitted with double Schechter function. The reduced χ^2 of a single Schechter fit compared to a double is 10.22 and 2.40 in the redshift range $0.3 < z < 0.5$, and 6.85 and 2.04 in the $0.5 < z < 1.0$ redshift bin. The parameters from the Schechter fits for the blue and red galaxy SMFs are listed in Tables 4 and 5. The uncertainties on the number densities are the result of a Monte Carlo analysis performed in the same way as described in Section 3.1, with an additional Monte Carlo to include the uncertainty in the colours. The uncertainties on the rest-frame magnitudes are a function of redshift, stellar mass and colour. Therefore, by including this additional Monte Carlo simulation we are factoring in changes in the number densities due to possible contamination in the *UVJ* selection as well as the reliability of the selection as a function of various properties (e.g. the uncertainties will be larger for objects with lower stellar mass). We discuss the blue and red SMFs, and how they compare to previous studies in Section 4.1.2.

3.3 The galaxy stellar mass function in high and low densities

The environment in which a galaxy lives plays a key role in its evolution. A galaxy in high density may be subjected to many processes which drive stellar mass build up (e.g. mergers) or affect SF (e.g. interactions and stripping) more frequently than a galaxy in low density. To investigate how stellar mass builds up in different environments we utilize the environmental information from the UDS (see Section 2.5; Lani et al. 2013).

Table 3. The double Schechter parameters for the total galaxy SMF. These parameters are plotted in Fig. 6.

Redshift range	M^*	$\log \phi_*^1$	α_1	$\log \phi_*^2$	α_2
$0.3 < z < 0.5$	10.90 ± 0.13	-3.51 ± 0.30	-1.59 ± 0.08	-2.59 ± 0.14	-0.71 ± 0.31
$0.5 < z < 1.0$	10.90 ± 0.11	-3.21 ± 0.19	-1.42 ± 0.06	-2.93 ± 0.13	-0.49 ± 0.48

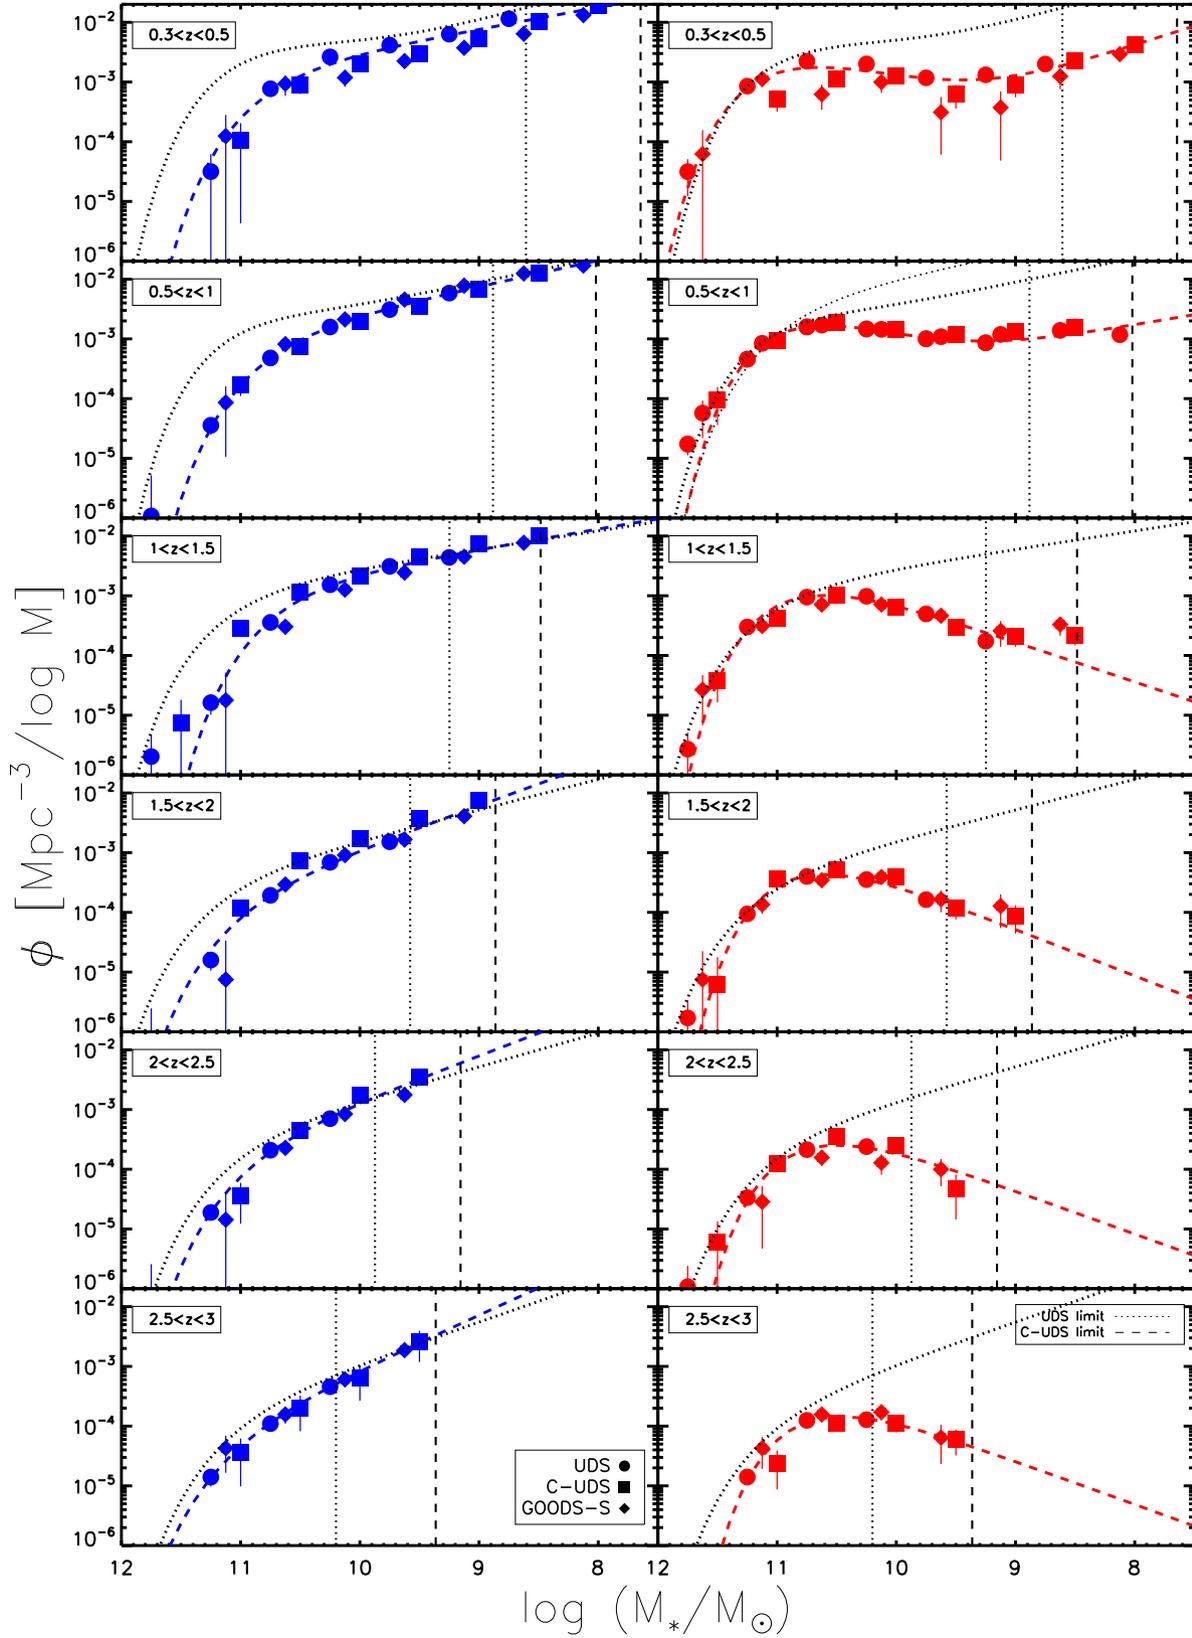

Figure 7. The galaxy SMF divided by UVJ selection for the UDS, the C-UDS and the GOODS-S. The left- and right-hand panels are the galaxy SMFs of blue and red galaxies, respectively. The circles are from the UDS, squares are from the C-UDS, and diamonds are from the GOODS-S. The dashed blue/red lines are the Schechter fits to combined data points. All fits are single Schechter fits with the exception of the red SMFs in the redshift range $0.3 < z < 1$. The dot/dash vertical lines are the stellar mass limits for the UDS and C-UDS data sets. The dotted black curves are the Schechter fits to the total galaxy SMF, from the relevant redshift bin, in Fig. 5.

Table 4. The single Schechter parameters for the blue and red galaxy SMFs.

Colour	Redshift range	M^*	$\log \phi_*$	α
Blue	$0.3 < z < 0.5$	10.83 ± 0.06	-3.31 ± 0.05	-1.41 ± 0.02
Blue	$0.5 < z < 1.0$	10.77 ± 0.03	-3.28 ± 0.03	-1.45 ± 0.01
Blue	$1.0 < z < 1.5$	10.64 ± 0.02	-3.14 ± 0.02	-1.37 ± 0.01
Blue	$1.5 < z < 2.0$	11.01 ± 0.06	-4.05 ± 0.07	-1.74 ± 0.02
Blue	$2.0 < z < 2.5$	10.93 ± 0.07	-3.93 ± 0.10	-1.77 ± 0.04

Red	$0.5 < z < 1.0$	10.77 ± 0.03	-4.11 ± 0.21	-1.37 ± 0.09	-2.75 ± 0.02	-0.27 ± 0.09

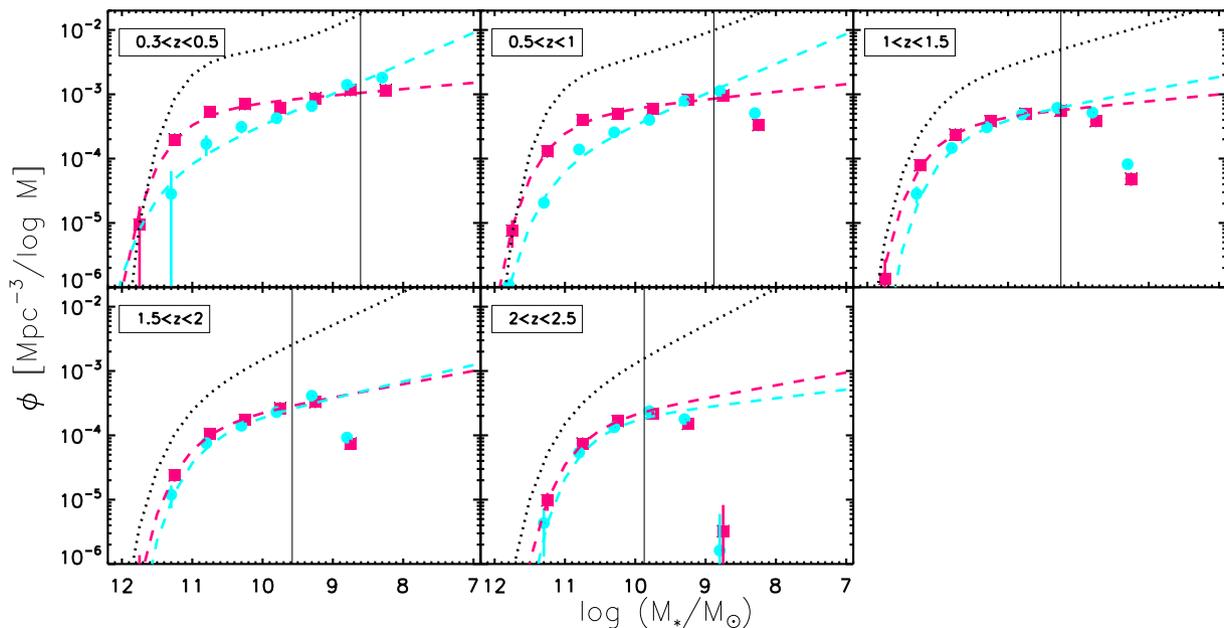

Figure 8. The galaxy SMF of galaxies in high and low densities in the UDS. The blue circles represent galaxies which reside in low densities and the pink squares represent galaxies which reside in high densities (as defined in Section 2.5). The dashed lines are the Schechter fits to the data, and the solid black line is the stellar mass limit of the UDS from Hartley et al. (2013). The dotted black curves are the Schechter fits to the total galaxy SMF from the relevant redshift bin.

Fig. 8 shows the galaxy SMFs of systems in high and low densities, excluding middle densities (see Section 2.5 and Table 1). The SMFs split by environment were completeness corrected as discussed in Section 2.4. The uncertainties were computed as in Section 3.1, with an additional bootstrap Monte Carlo analysis to quantify the uncertainties from the environments. This uncertainty was computed by randomly re-sampling the environments and then recalculating the number densities. The result of this was then added in quadrature to the stellar mass and redshift Monte Carlo results to get the final uncertainties.

Our results show little difference in the galaxy SMF of systems in different environments at redshifts of $z > 1$. The Schechter

fits to the galaxies in dense environments are almost identical to those of galaxies in low densities at these redshifts (see Table 6 for the Schechter function fit parameters). For redshifts of $z < 1$ there is evidence of the high-mass end of the galaxy SMF being more dominated by galaxies in dense environments, although the uncertainties are large. As discussed in Section 2.5, the environments in this study can only be used to statistically look at the whole galaxy population. It is possible there is contamination between our high- and low-density selection and this could be playing a role in our results. One concern is that the contamination will be a function of redshift and stellar mass, hence the shape of the environment SMF could be altered in different ways in different environment bins. In

Table 6. The single Schechter parameters for the high- and low-density SMFs.

Redshift range	Density bin	M^*	$\log \phi_*$	α
$0.3 < z < 0.5$	High	11.20 ± 0.07	-3.59 ± 0.07	-1.10 ± 0.04
$0.5 < z < 1.0$	High	11.17 ± 0.05	-3.70 ± 0.05	-1.12 ± 0.03
$1.0 < z < 1.5$	High	11.06 ± 0.04	-3.80 ± 0.05	-1.11 ± 0.03
$1.5 < z < 2.0$	High	11.02 ± 0.09	-4.19 ± 0.11	-1.21 ± 0.08
$2.0 < z < 2.5$	High	10.83 ± 0.14	-4.14 ± 0.20	-1.20 ± 0.25
$0.3 < z < 0.5$	Low	11.50 ± 0.65	-4.55 ± 0.43	-1.48 ± 0.06
$0.5 < z < 1.0$	Low	11.19 ± 0.18	-4.38 ± 0.16	-1.47 ± 0.05
$1.0 < z < 1.5$	Low	10.90 ± 0.08	-3.91 ± 0.07	-1.22 ± 0.04
$1.5 < z < 2.0$	Low	10.94 ± 0.13	-4.29 ± 0.15	-1.26 ± 0.11
$2.0 < z < 2.5$	Low	10.71 ± 0.20	-4.15 ± 0.27	-1.14 ± 0.39

particular at high redshifts, and low stellar masses, the photometric uncertainties will be large and could have more of an impact. To test how this could change the results of this study we take each galaxy and model its redshift uncertainty as Gaussian. Then a new redshift is selected from this distribution 1000 times, and for each new redshift we determine whether or not the object would remain in its original density bin. Then, the average fraction of galaxies which leave their original density bin is calculated as a function of redshift and stellar mass. Using this fraction an upper and lower bound is computed for each number density in Fig. 8. The lower bound is simply the number density after the removal of the average fraction of galaxies which are removed from their original density bin. The upper bound is taken as the original number density plus the average fraction of galaxies which are removed from the opposite density bin. We find that this upper and lower bound is never larger than the uncertainty on the number densities with the exception of the lowest mass bins in the redshift range $1 < z < 2$. Here we find that the removal of galaxies based on their photometric uncertainties could produce a slightly lower number density in the lowest density environment. However even taking this into account the high- and low-density SMFs are still consistent with being the same at low stellar masses. The excess of massive galaxies is thus not affected. The interpretation of these results is discussed further in Section 4.3.

3.4 The evolution of the mass function for galaxies with different structural parameters

The SMF of galaxies with different structural parameters gives us insight into the growth of these populations over time, as well as how these objects contribute at different stellar masses. CANDELS provides a deep data set for computing the number densities of galaxies over a large range of stellar masses, as well as high-resolution imaging for obtaining accurate structural parameters. Therefore CANDELS is an optimal data set for investigating the SMF of systems with different structural properties. Figs 9 and 10 show the galaxy SMF of galaxies from the two CANDELS fields, split by asymmetry and Sérsic index, respectively. The Sérsic indices are from van der Wel et al. (2012) and the asymmetries were computed using the CAS code as in Conselice (2003) and Mortlock et al. (2013) (see Section 2.6). The division in asymmetry is such that galaxies with $A > 0.35$ are the most disturbed population (see Conselice 2003). Also, systems with Sérsic index $n > 2.5$ tend to be spheroidal/bulge dominated population and galaxies while $n < 2.5$ are the disc/peculiar population (see e.g. Lee et al. 2013; Mortlock et al. 2013; Bruce et al. 2014).

The simulations described in Section 3.1 were used to correct these SMFs for incompleteness. These simulations contained galaxies with both exponential profiles ($n = 1$) and de Vaucouleurs profiles ($n = 4$) for the C-UDS galaxies, and with a range of ellipticities for the GOODS-S galaxies. Separate completeness fractions were computed for these two types of galaxies. The completeness fractions for galaxies with exponential profiles were used to correct the $n < 2.5$ galaxies, i.e. it was assumed that the exponential profiles represent low Sérsic index galaxies. The completeness fractions for galaxies with de Vaucouleurs profiles were used to correct the number densities of $n > 2.5$ galaxies, i.e. it was assumed that de Vaucouleurs profiles represent high Sérsic index galaxies. For GOODS-S it was assumed galaxies with high ellipticity (ellipticity > 0.5), i.e. elongated objects, will have completeness corrections similar to exponential profile objects. For galaxies with low ellipticity (ellipticity < 0.5), i.e. rounded objects, it was assumed galaxies will have completeness corrections similar to objects with de Vaucouleurs profiles.

Broadly speaking, galaxies with high asymmetries also have low Sérsic indices, whereas galaxies which are more symmetric have higher Sérsic indices (e.g. Mortlock et al. 2013). Therefore, the same correction was used for the $A > 0.35$ ($A < 0.35$) number densities as was used for the $n < 2.5$ ($n > 2.5$) number densities. If we perform the same analysis without the completeness correction (i.e. fitting down to the stellar mass limit), the Schechter function parameters remain virtually unchanged. One particular concern is that the low-mass slope will be least robust due to difficulties in measuring the structure of low-mass objects. When the Schechter fits were performed without completeness corrections, and only to stellar masses the data are complete, α was changed by typically less than 5 per cent and always remained within the uncertainty of the value from fitting the completeness corrected SMF. Tables 7, 8 and 9 list the values of the Schechter parameters for the fits to the structural SMFs.

Galaxies with low asymmetry dominate at all masses and at all redshifts (over the redshift range $1 < z < 3$). The evolution of the low asymmetry SMF is very similar to the evolution of the total SMF simply because most galaxies do not have extreme asymmetries by definition. Conversely, the asymmetric population contributes very little to the total mass budget in this redshift range. There is very little evolution in the number densities of these galaxies in our redshift range.

There is a clear difference in the galaxy SMFs of high and low Sérsic index galaxies. The number densities of low Sérsic index galaxies are well fitted with a single Schechter function, whereas the number densities of high Sérsic index galaxies (orange squares and diamonds in Fig. 10) are not. The reduced χ^2 values for the double

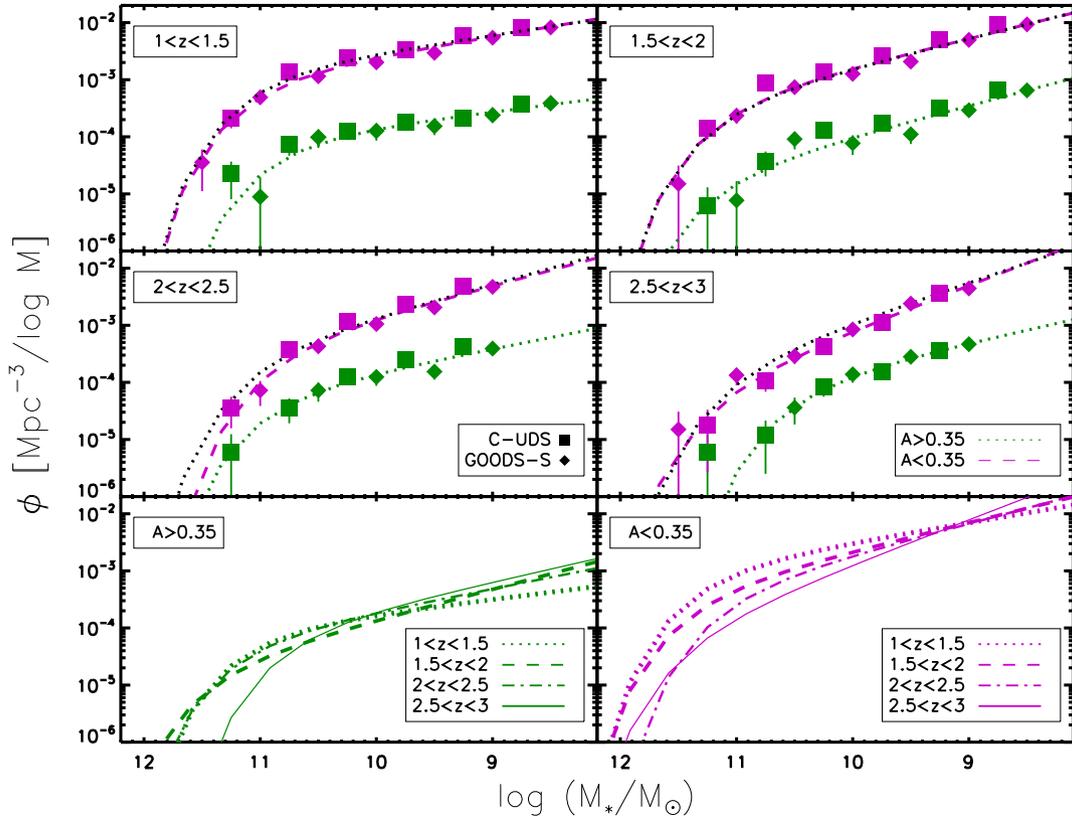

Figure 9. The galaxy SMF of the C-UDS and GOODS-S galaxies separated into high asymmetry ($A < 0.35$, purple squares and diamonds and purple dashed line) and low asymmetry ($A > 0.35$, green squares and diamonds and green dotted line). The dotted black curves are the Schechter fits to the total galaxy SMF, from the relevant redshift bin, in Fig. 5. The bottom panels compare the Schechter functions in each redshift bin. All fits are single Schechter fits. The asymmetries are described in Section 2.6.2.

Schechter fits are 1.53, 1.69, and 1.38 compared to 5.45, 5.09, and 3.23 for the single Schechter fits. It has been found extensively in the literature that the total galaxy SMF, and the SMF of red/passive galaxies, show a clear double Schechter function form (Drory et al. 2009; Baldry et al. 2012; Ilbert et al. 2013; Muzzin et al. 2013; Tomczak et al. 2014, although to what redshift this persists is still in debate). In this study the same feature is reported in the SMF of galaxies with $n > 2.5$. In the highest redshift bin the number densities are closer to the form of a power law, although this could be the result of poor number statistics at the high-mass end. From redshifts $z \sim 2.5$ to $z \sim 1$ there is rapid evolution at the high-mass end of the SMF of systems with high Sérsic indices, such that high-mass galaxies with $n > 2.5$ appear to be forming quickly.

3.5 The stellar mass density

The stellar mass density (SMD) of the total galaxy population is a useful quantity for investigating the way in which the total stellar mass in the Universe is evolving. Furthermore, by computing the SMD of different galaxy populations we can determine which types of galaxies dominate the stellar mass budget at which epochs, as well as similarities between the growth of different systems. In this study the SMD was computed using the equation

$$\rho_* = \int_{M_*=7}^{M_*=12} M_* \times \phi(M_*) dM_*, \quad (7)$$

where ρ_* is the SMD, $\phi(M_*)$ is the Schechter function determined from fitting as discussed in previous sections, and M_* is the stellar

mass. Fig. 11 shows the total SMD along side several recent literature results. The uncertainties on the SMDs were computed from Monte Carlo shuffling of the Schechter function parameters along a Gaussian with a width equal to the 1σ measured uncertainty on that parameter. This was done 100 times and then the SMD for each of these Monte Carlo realizations was computed. The final uncertainty was the standard deviation of these realizations.

A steady increase of the total SMD is shown in Fig. 11. This increase is the build-up of all stellar mass in the Universe. Taking the SMD at redshift $z = 0$ from the relation in Tomczak et al. (2014) we find that at redshift $z = 1.25$, 35 per cent of the SMD in the Universe has been built up. By redshift $z = 0.75$, 58 per cent of the total SMD had been built up, i.e. ~ 50 per cent of the total SMD is formed around redshift of $z = 1$. Fig. 11 shows that there is a large difference between the SMD from Mortlock et al. (2011) and Santini et al. (2012) and the remainder of the SMDs plotted, including the SMD computed in this work. Mortlock et al. (2011) and Santini et al. (2012) used data from small area surveys and therefore had difficulty constraining the high-mass turnover (see Fig. 6) and therefore stellar mass would be added to the total SMD at the high-mass end. We therefore argue that the higher values for SMD are a result of poor constraints on the high-mass end of the galaxy SMF.

The SMD for the total, star-forming, quiescent, high and low Sérsic index, high and low asymmetry, and high- and low-density galaxy populations is also plotted as a function of redshift in Fig. 12. Considering the total galaxy population split into star-forming and

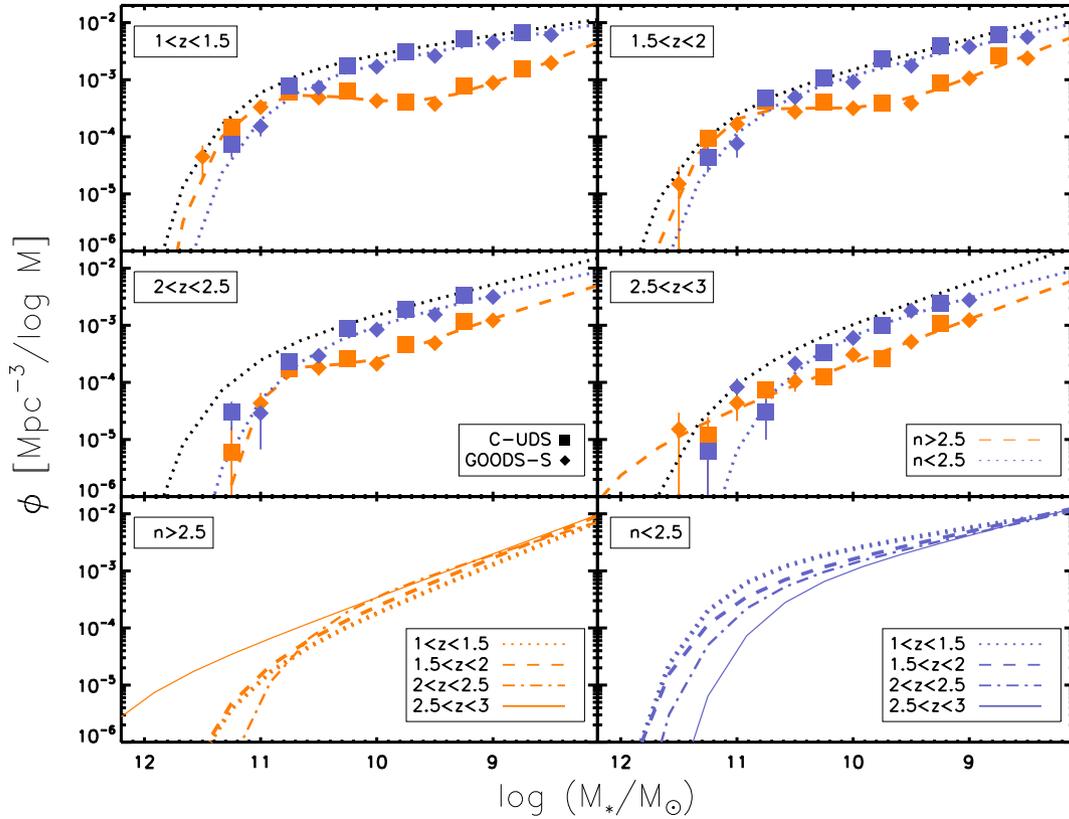

Figure 10. The galaxy SMF of the C-UDS and GOODS-S galaxies separated into high Sérsic index ($n > 2.5$, orange squares and diamonds and orange dashed line) and low Sérsic index ($n < 2.5$, blue squared and diamonds and blue dashed line). The dotted black curves are the Schechter fits to the total galaxy SMF, from the relevant redshift bin, in Fig. 5. The bottom panels are comparisons of the fits to the high and low Sérsic indices fits in each redshift bin. All fits to the $n < 2.5$ SMFs are single Schechter fits. All fits to the $n > 2.5$ are double Schechter fits with the exception of highest redshift bin. The Sérsic indices are from van der Wel et al. (2012), see Section 2.6.1.

Table 7. The single Schechter parameters for the high and low Sérsic indices SMFs.

Redshift range	Sérsic index	M^*	$\log \phi_*$	α
$1.0 < z < 1.5$	$n > 2.5$	11.60 ± 0.27	-4.18 ± 0.20	-1.30 ± 0.06
$1.5 < z < 2.0$	$n > 2.5$	11.74 ± 0.42	-4.71 ± 0.33	-1.51 ± 0.06
$2.0 < z < 2.5$	$n > 2.5$	11.09 ± 0.24	-4.45 ± 0.27	-1.55 ± 0.09
$2.5 < z < 3.0$	$n > 2.5$	11.98 ± 1.44	-5.52 ± 1.26	-1.76 ± 0.09
$1.0 < z < 1.5$	$n < 2.5$	10.78 ± 0.08	-3.28 ± 0.10	-1.33 ± 0.05
$1.5 < z < 2.0$	$n < 2.5$	10.85 ± 0.10	-3.61 ± 0.12	-1.45 ± 0.05
$2.0 < z < 2.5$	$n < 2.5$	10.68 ± 0.12	-3.60 ± 0.17	-1.46 ± 0.09
$2.5 < z < 3.0$	$n < 2.5$	10.42 ± 0.14	-3.60 ± 0.20	-1.52 ± 0.11

Table 8. The double Schechter parameters for the high Sérsic indices SMFs.

Redshift range	Sérsic index	M^*	$\log \phi_*^1$	α_1	$\log \phi_*^2$	α_2
$1.0 < z < 1.5$	$n > 2.5$	10.80 ± 0.12	-4.93 ± 0.49	-1.82 ± 0.20	-3.24 ± 0.09	-0.32 ± 0.30
$1.5 < z < 2.0$	$n > 2.5$	10.78 ± 0.15	-4.79 ± 0.40	-1.81 ± 0.15	-3.49 ± 0.11	-0.31 ± 0.42

quiescent galaxies, it is clear that the increase in the total population is driven by the rapid growth of the quiescent population. The SMD of the star-forming population remains roughly constant over our whole redshift range. Furthermore, there is a clear cross-over around redshift of $z \sim 2$ where the quiescent population becomes dominant over the star-forming population.

A similar cross-over behaviour is found for the SMD of galaxies with high and low Sérsic index. At $z > 2$ there is not a

substantial difference between the SMD of these two types of system. However, there is evidence that the SMD of high and low Sérsic index galaxies begins to converge at $z < 2$. Several previous studies (e.g. Buitrago et al. 2008; Bruce et al. 2012; Mortlock et al. 2013) have found a cross-over in the dominance of galaxies with disc and spheroidal morphology (which are traditionally considered to be low and high Sérsic index galaxies) around this redshift.

Table 9. The single Schechter parameters for the high and low asymmetry SMFs.

Redshift range	Asymmetry	M^*	$\log \phi_*$	α
$1.0 < z < 1.5$	$A > 0.35$	10.86 ± 0.20	-4.40 ± 0.19	-1.25 ± 0.09
$1.5 < z < 2.0$	$A > 0.35$	11.17 ± 0.35	-4.99 ± 0.33	-1.54 ± 0.08
$2.0 < z < 2.5$	$A > 0.35$	10.94 ± 0.26	-4.55 ± 0.28	-1.40 ± 0.12
$2.5 < z < 3.0$	$A > 0.35$	10.51 ± 0.25	-4.37 ± 0.31	-1.46 ± 0.16
$1.0 < z < 1.5$	$A < 0.35$	11.05 ± 0.08	-3.31 ± 0.10	-1.34 ± 0.04
$1.5 < z < 2.0$	$A < 0.35$	11.14 ± 0.11	-3.72 ± 0.13	-1.50 ± 0.04
$2.0 < z < 2.5$	$A < 0.35$	10.86 ± 0.13	-3.68 ± 0.18	-1.54 ± 0.08
$2.5 < z < 3.0$	$A < 0.35$	11.16 ± 0.24	-4.36 ± 0.30	-1.79 ± 0.07

Figure 11. The total SMD as a function of redshift. Overplotted for comparison are various results from the literature (see legend). Where necessary, we converted the literature values of SMD to a Chabrier IMF.

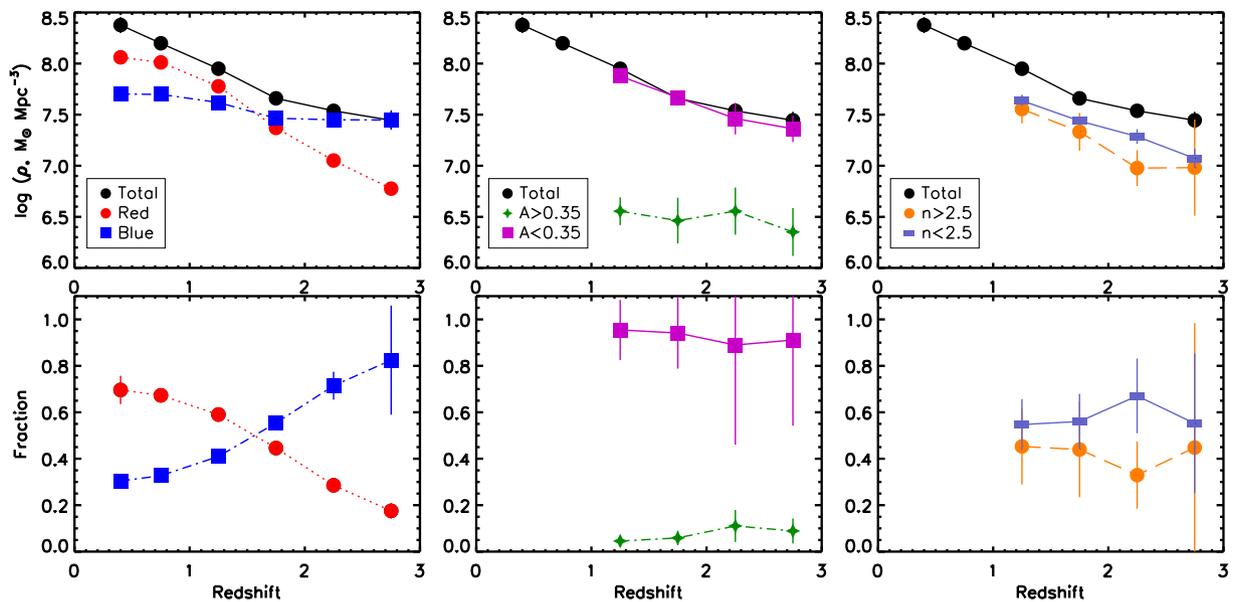

For galaxies of low asymmetry, the evolution of the SMD is very similar to that of the total galaxy population. This is not a surprise as high asymmetry is selecting galaxies which are in the most peculiar stages of a merger whereas low asymmetry is selecting the remainder of the galaxy population. Interestingly, the SMD of systems with high asymmetry is roughly constant across our redshift range. This is similar to the behaviour of the star-forming SMD (and SMF). This could indicate that, in a similar way to the star-forming and quiescent SMF, galaxies move along and/or off the high asymmetry SMF in such a way that the evolution of the high asymmetry SMF is stellar mass independent.

4 DISCUSSION

4.1 Comparison to the literature

4.1.1 The total galaxy SMF

The Schechter function parameters describe the growth of the total galaxy population (ϕ^*), as well as the evolution of high-mass (M^*) and low-mass galaxies (α). From high to low redshift, galaxies are forming and growing in stellar mass hence an increase in ϕ^* should be seen. The evolution of this parameter has long been established

Figure 12. Top panels: the SMD as a function of redshift for the total, star forming, quiescent, high and low Sérsic index, and high and low asymmetry galaxy populations. Bottom panels: the fraction of the total SMD from the total, star forming, quiescent, high and low Sérsic index and high and low asymmetry galaxy populations. See legend for the meaning of the points and colours.

(e.g. Fontana et al. 2004, 2006; Drory et al. 2005; Borch et al. 2006; Bundy et al. 2006; Pérez-González et al. 2008; Kajisawa et al. 2009; Marchesini et al. 2009; Ilbert et al. 2010, 2013; Caputi et al. 2011; Mortlock et al. 2011; Santini et al. 2012; Davidzon et al. 2013; Muzzin et al. 2013; Duncan et al. 2014; Tomczak et al. 2014), but with field to field variation there have been differences in the absolute value (left-hand panel of Fig. 6). In this plot the results from Ilbert et al. (2013) and Tomczak et al. (2014) are the sum of two normalizations from a double Schechter fit and so are not directly comparable. It is noted that differences in the form on the Schechter function further highlight the spread in results.

Some of the earlier studies of the galaxy SMF have showed that the value of α is steep and gets steeper as redshift increases (e.g. Fontana et al. 2004, 2006; Marchesini et al. 2009). However the absolute value of α , and at what redshift the evolution continues to can depend greatly on the stellar mass limit of the survey. As technology has advanced, and observations of faint galaxies become routine, it has become clear that α steepens out to redshifts of $z \sim 3$ (Kajisawa et al. 2009; Mortlock et al. 2011; Santini et al. 2012; Tomczak et al. 2014) and higher (Caputi et al. 2011; Santini et al. 2012; Duncan et al. 2014). This is confirmed in this work and indicates that low stellar mass galaxies contribute significantly to the total stellar mass budget in the Universe at these epochs. The flattening of α with time is likely a result of low stellar mass galaxies increasing in stellar mass via merging or some process such as *in situ* SF.

While the parameters ϕ^* and α show strong evolution in our redshift range, the value of the characteristic turnover M^* remains roughly constant from a redshift of $z = 0.3$ to 3 (middle panel of Fig. 6). The lack of evolution of M^* implies that although the number density of massive galaxies is increasing over time due to the increase in normalization, the knee of the mass distribution is not evolving. What this means is that the typical stellar masses of systems around the knee of the galaxy SMF are not evolving with redshift. This is also evident when comparing the high-mass end of the galaxy SMF at high redshift to that of the local Universe. The number densities of the most massive galaxies ($M_* > 10^{11.5} M_\odot$) evolve very little from $z \sim 3$ to 0. Furthermore, galaxies with stellar masses of $M_* > 10^{11} M_\odot$ have reached their local number density between redshifts of $z = 1-2$. The lack of evolution is consistent with downsizing (e.g. Cowie et al. 1996), where the most massive galaxies form their stellar mass first.

There is a huge amount of work in the literature dedicated to studying the galaxy SMF, however, we choose to compare to the most recent literature results here, which also probed similar redshift range to this study. The main motivation for this is to compare to studies which either are (a) complete to similar stellar masses as in this work for a good comparison to α or (b) from large area surveys for a good comparison to M^* . Furthermore, by being selective in our comparison we are able to compare to studies which fit to similar stellar population models (BCO3 models, with exponentially declining SF histories). The only differences which could cause problems are the inclusion of emission lines and differences in the IMF. Mortlock et al. (2011), Santini et al. (2012) and Muzzin et al. (2013) use a different IMF to this study however this is always accounted for when comparing results. Finally, Ilbert et al. (2013) and Tomczak et al. (2014) include nebular emission lines when computing galaxy properties however as noted in Section 2.3 the presence of nebular emission has little impact on this work.

Although there is good agreement on the evolution of the Schechter function parameters there are generally differences in the absolute values as shown by the comparison of the literature

results in Fig. 6 (see legend). In terms of M^* and α the biggest differences are likely the result of the different depths and areas covered by surveys. Large differences in M^* will result from poor constraint of the high-mass end of the galaxy SMF in surveys with small areas. This is supported by the fact that the results from the two smallest areas, Mortlock et al. (2011) and Santini et al. (2012), find the highest values for M^* . In this work the large area of the UDS is utilized to constrain M^* . Comparing our results for M^* to Muzzin et al. (2013), who used a comparable survey area and fitted with a single Schechter function (hence the parameters are directly comparable), we find excellent agreement across our whole redshift range. Davidzon et al. (2013) construct the galaxy SMF over the much larger area of VIMOS Public Extragalactic Redshift Survey (VIPERS). This allows for excellent constraint on the high-mass turnover and where we overlap in redshift our values of M^* differ by at most ~ 0.1 dex.

Often, survey area is compromised for depth, as having a deep survey is key for constraining the low-mass slope α . In this work, the CANDELS data allowed us to fit to low stellar masses, and hence this work improves upon other studies which have only large area data (e.g. Ilbert et al. 2013; Muzzin et al. 2013). In comparison to Mortlock et al. (2011), who have the deepest data set which is fit by a single Schechter function, excellent agreement is found for the low-mass slope. Tomczak et al. (2014) have a similar stellar mass limit to this study and fitted with a double Schechter function across their whole redshift range. The double Schechter fits to the redshift range $0.3 < z < 1.0$ (see Section 3.4) are in good agreement in α at $z \sim 1$.

Tomczak et al. (2014) not only have a similar stellar mass limit to this study, they also combine deep data with wide area data to constrain the high-mass turnover as we do in this work. However, the wide UDS data used here are $\sim 0.5 \text{ deg}^2$ larger in area than the NEWFIRM Medium-Band Survey which is crucial for finding the rarest high-mass galaxies. Therefore, in this work we have a better constraint on both M^* and α thanks to the combination of both deeper and larger area surveys than previous studies.

4.1.2 The blue and red galaxy SMFs

In this study the total galaxy SMF was divided into blue and red galaxies using the UVJ selection technique. This division was used as a proxy for the SF activity within a system. The blue, star-forming SMF shows very mild evolution in shape at $z < 2$ and little evolution in normalization. At redshifts of $z > 2$ the slope of the star-forming SMF steepens, and the high-mass turnover increases (see Table 4), however there is very little further evolution. The lack of evolution of the star-forming SMF is reflected in the almost constant SMD of star-forming galaxies (Fig. 12). This is in agreement with, e.g. Borch et al. (2006), Bell et al. (2007), Peng et al. (2010b), Mortlock et al. 2011, Moustakas et al. (2013), Ilbert et al. (2013), Muzzin et al. (2013) and Tomczak et al. (2014), who have shown that at redshift of $z > 2$ the SMD of star-forming systems begins to decrease. Furthermore, some studies have found the blue SMF to have a double Schechter function form (Drory et al. 2009, Ilbert et al. 2013; Tomczak et al. 2014), however we see no evidence for either of these trends in our study.

The red, quiescent SMF evolves very little in M^* whereas the low-mass slope becomes steeper with look back time. In our lowest redshift bin, $0.3 < z < 0.5$, the number density of galaxies with $M_* \sim 10^{11} M_\odot$ has grown by only a factor of ~ 1.5 since redshift of $z \sim 2$, whereas the number density of galaxies with $M_* \sim 10^{9.5} M_\odot$ has increased by a factor of 5. This suggests

that the growth of quiescent galaxies is mass dependent, i.e. there are two separate high-mass and low-mass populations growing in stellar mass. This result is in agreement with many literature results. The bimodal form of the red SMF was first noted in Drory et al. (2009) and has since been shown in the local Universe (Baldry et al. 2012) and out to redshift of $1 < z < 1.5$ (Ilbert et al. 2013; Muzzin et al. 2013; Tomczak et al. 2014). The most massive galaxies build up their stellar mass early in the life of the Universe, and also quenched earlier. However the number density of low-mass galaxies build up rapidly in our redshift range hence low-mass systems are quenching quickly. Furthermore, the normalization, ϕ^* , increases by almost an order of magnitude from redshift $z = 3$ to 0.3, reflecting the rapid build-up of the population of galaxies whose SF has ceased.

The mass-dependent growth of red systems leads to a double Schechter function form to the quenched galaxy SMF in the lowest two redshift bins. There is hint of the double Schechter feature in the $1 < z < 1.5$ redshift bin, however it is unclear if this feature is present above a redshift of $z = 1$ as it is close to the completeness limit. The double Schechter function form is likely the result of two distinct galaxy populations dominating at different stellar masses. Peng et al. (2010b) suggested these two quenched populations are either mass quenched or quenched as a result of their environment (see Section 4.3). In this picture, the low-mass end is dominated by environment quenched galaxies, hence the upturn in the quenched galaxy SMF is directly linked to the importance of the environment quenching process. Although we cannot say anything about environment quenching at $z > 1$ here, the upturn seems more prominent at $z \sim 0.4$ compared to at $z \sim 0.75$. This could be an indication that environment quenching is becoming more important in the lowest redshift bin (Muzzin et al. 2013).

The rapidly changing SMF of red, or quenched galaxies, and the lack of evolution of blue or star-forming galaxies, is an indication of a balance between the growth of galaxies on the SF main sequence and the processes which shut off SF. When systems are quenched, they move off the star-forming SMF and on to the quenched SMF. The cessation of SF is a function of stellar mass, yet this is not reflected in the shape of the star-forming SMF. The build-up of stellar mass in star-forming galaxies must happen in such a way that as galaxies move along the star-forming SMF (i.e. grow in stellar mass), the number density of galaxies of all stellar masses is preserved.

The impact of contamination within the *UVJ* selection has been discussed in Sections 2.3.2 and 3.2. However, as a final test of how robust to contamination the results discussed here are, a Monte Carlo simulation is performed. In this simulation a given percentage of random objects are moved from the red to blue bin, or vice versa, 500 times. The approach is complementary to the Monte Carlo which produces the uncertainties on the number densities. In the latter case the uncertainty on the number densities is representative of how the *UVJ* selection impacts these results as a function of, not only redshift and stellar mass, but also of data set. In our second approach we are testing how robust our results are to a certain level of contamination.

When we shift 5 per cent of objects from red to blue and vice versa this has no impact on the results of this work. When 10 per cent of objects are shifted to the opposite colour bin we find this does have some impact on the fitted Schechter function parameters of the red SMFs. The low-mass slope becomes less shallow at redshift of $z > 1$ and M^* is increased by ~ 0.2 dex. However, the change in the absolute value of the Schechter function parameters does not affect any results discussed in this section e.g. the double Schechter

function form of the red SMFs and the steepening of α of the red SMF with redshift. Furthermore, the change is not enough to impact the SMD results discussed in Section 3.5. If the percentage of objects shifted between colour bins is changed to 20 per cent the impact on the Schechter function parameters is more severe. M^* is increased by ~ 0.4 dex and α becomes steep (-1.3 to -0.9) at redshifts of $z > 1$. This in turn alters the SMDs by $\sim 0.2 - 0.3$ dex. However, at $z < 1$ the red SMF is impacted less and still retains the double Schechter function form.

4.2 The link between quenching and structure

There is debate in the literature regarding the link between passivity and the structure of a galaxy. This is frequently cast in terms of the presence of a bulge correlating with a galaxy being passive (e.g. Bell et al. 2012; Cheung et al. 2012; Barro et al. 2013; Fang et al. 2013; Lee et al. 2013; Lang et al. 2014; Williams et al. 2014). There are exceptions e.g. the presence of passive discs (e.g. Bruce et al. 2012, 2014; McLure et al. 2013) and hence there is still question as to if passivity is caused by the presence of a bulge or vice versa. In this work, similarities are found between the shape of the galaxy SMF of high Sérsic index galaxies (i.e. bulge/spheroidal galaxies at these redshifts, see Lee et al. 2013; Mortlock et al. 2013; Bruce et al. 2014) and the red, or quenched, SMF. It is also shown in this study that the SMDs of red systems and $n > 2.5$ systems are comparable. This suggests that a similar amount of stellar mass is tied up in red galaxies and $n > 2.5$ galaxies across our redshift range.

To discern if these two populations are linked we plot the fraction of galaxies which are red and have high Sérsic indices, and the fraction of high Sérsic index galaxies which are red, as a function of stellar mass and redshift (see Fig. 13). The uncertainties in this plot were computed from varying the uncertainties on the redshifts, stellar mass, colours and Sérsic index with standard deviation equal to the 1σ measured uncertainty of each property. This Monte Carlo analysis was done 100 times, and the fraction was recalculated for each run. The final uncertainties on the fractions in Fig. 13 were the standard deviations of these Monte Carlo runs. There is no evidence of a trend with redshift for red galaxies with high Sérsic index. For high Sérsic index galaxies which are red, the fraction increases as a function of redshift for both stellar masses. In the top panel of Fig. 13 the relationship between a galaxy being red and having high Sérsic index is a strong function of stellar mass. Of the galaxies with $n > 2.5$ and stellar mass $M_* \sim 10^{11} M_\odot$, ~ 90 per cent have red colours, and ~ 75 per cent of red galaxies have $n > 2.5$. These percentages drop to roughly 25 per cent for red galaxies with $n > 2.5$, and almost nothing for the high Sérsic index, red galaxies, when considering low-mass systems.

Our results suggest that, if indeed high Sérsic index links to the cessation of SF, this is only true in massive galaxies and not in low-mass systems. This is supported by the Devereux et al. (2009) who construct the *K*-band luminosity function and show that bright/faint systems are dominated by elliptical/disc morphologies. These results are indicative of mass-dependent processes at play. A possible scenario is that for high-mass galaxies some process (or processes) act on a galaxy and instigate the formation of a bulge and also quenches that system. In low-mass galaxies bulge formation does not link to the cessation of SF. We cannot discern from these results if quenching and bulge formation happens simultaneously or not in massive galaxies. However we suggest a possible link to feedback from black holes. The mass of a black hole scales with the mass of a galaxy and the bulge (e.g. Ferrarese & Merritt 2000; Gebhardt et al. 2000) and hence feedback from a massive black hole could

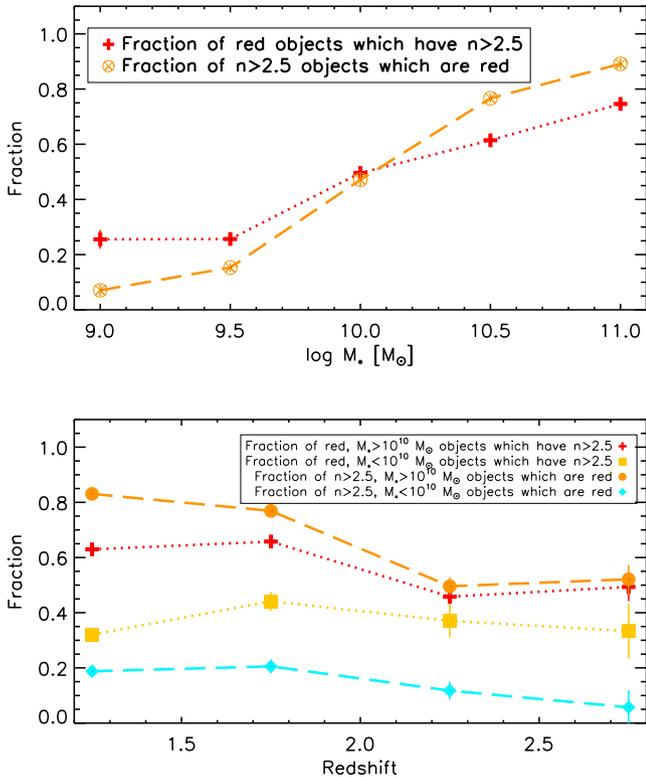

Figure 13. The fraction of galaxies which are red and have high Sérsic index (red crosses joined by dotted lines) and the fraction of galaxies which have high Sérsic index and are red (orange circles with crosses joined by dashed lines). The top panel shows these fractions as a function of stellar mass. The bottom panel shows these fractions as a function of redshift and split by stellar mass. See legend for symbol descriptions.

result in the formation of a bulge whilst also being powerful enough to shut off SF. However, our results suggest that in a less massive galaxy the process responsible for bulge formation, e.g. the black hole feedback, would not be strong enough to remove/cut off a galaxies gas supply allowing SF to continue.

4.3 The link between quenching and environment

A picture is beginning to emerge regarding the role environment plays in quenching galaxies. In the local Universe the fraction of quenched galaxies is high for massive systems, or if a galaxy lives in high-density environments (Baldry et al. 2006; Peng et al. 2010b). This suggests two separate ‘mass’ and ‘environment’ quenching

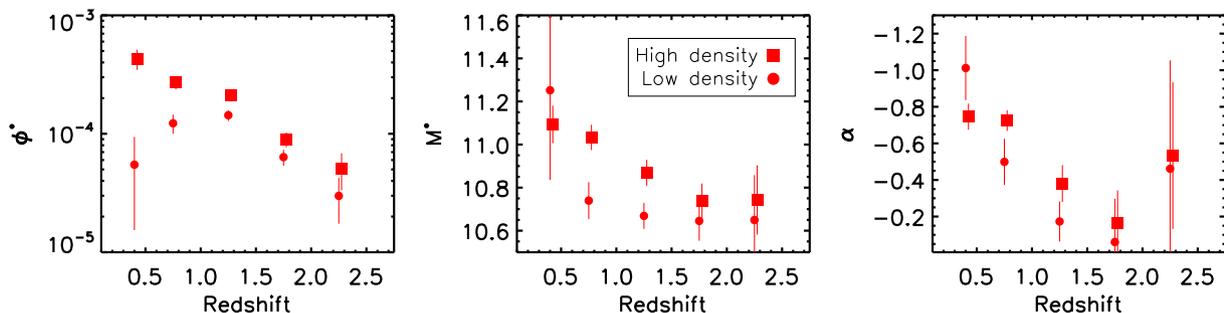

Figure 14. The Schechter function parameters from fits to the number densities of red, high-density (red squares) galaxies, and red, low-density (red circles) galaxies.

processes. These two processes are separable, and that the evolution of the galaxy SMF of blue and red galaxies can be explained with these two processes even out to high redshift (e.g. Ilbert et al. 2013; Scoville et al. 2013). There is also discussion in the literature regarding a comparable theory of separate quenching processes (e.g. Dekel & Burkert 2014; Woo et al. 2014). These studies suggest quenching channels which depend on halo mass and structure. The halo mass channel is supported by observations of differences in passivity in central and satellite galaxies (e.g. Woo et al. 2014), and also supported by theory (e.g. Dekel & Birnboim 2006). The relationship between quenching and structure is discussed in detail in Section 4.2.

To explore the role that environment plays in quenching and shaping the galaxy SMF, we utilized the environments in the UDS field (see Section 2.5) to compute the number densities of red galaxies in the high- and low-density environments. These number densities were fitted with a Schechter function, the parameters for which are shown in Fig. 14. At $z > 1.5$ the two galaxy SMFs are consistent with one another. The uncertainties are large, but environment will have a weaker impact on galaxies at higher redshifts as the densest structures have yet to form, hence this is expected and is consistent with Fig. 8 where the two galaxy SMFs are identical at $z > 1.5$.

Thanks to the excellent number statistics in the UDS we can still constrain the high-mass end of these SMFs even after this division. However, the difficulty here lies in the shallower depth of the UDS (e.g. compared to the CANDELS data used in this work) which creates problems when drawing conclusions from the low-mass slope. The uncertainties on α are large, therefore it can only be tentatively suggested that, at $0.5 < z < 1.5$, Fig. 14 hints at a steeper low-mass slope in high density, compared to low density. Again, it is stressed that the uncertainties mean we can say little more about α , however what is hinted at by the data does make sense in the context of environment quenching. The total quenched SMF shows a steep faint end slope (right-hand panel of Fig. 14), and in Peng et al. (2010b) it is suggested that low-mass satellite galaxies are the cause of this. These systems are starved of their SF fuel by e.g. gas stripping or harassment in high density and hence we would expect a steeper faint end slope in higher density environments.

In the middle panel of Fig. 14 the high-mass turnover is clearly higher for the galaxies which are, on average, in higher densities in the redshift range $0.5 < z < 1.5$. The larger values of M^* are indicative of high density causing the build-up of high-mass, red galaxies. Fig. 8 shows that the number densities of the total high-mass population in high densities are larger than in low-density environments. In this study it is shown that this is also true for the quenched galaxy population. The fact that there is an excess of quenched galaxies in high densities, not just in the total population

of galaxies in high densities, links environment to the cessation of SF in a galaxy. This increased quenching efficiency could be linked to processes which occur more frequently in high-density environments, such as mergers or mass quenching due to hotter haloes.

One caveat of this work is that photometric redshifts are used for computation of environments, and hence the contamination between low and high density is higher than ideal for this test. The same test as in Section 3.3 is performed on the red, high- and low-density SMFs. When adjusting the number densities for the possible fraction of galaxies lost/gained in a given density bin due to uncertainties on the photometric redshifts we find no impact on our conclusions regarding M^* . However, the value of α for the high density, red SMF, in the redshift bin $1 < z < 1.5$ is reduced and is consistent with the value of α for the low-density red SMF. This further stresses the difficulty with drawing any conclusions from the low-mass slope of quenched galaxies in different environments. Furthermore, contamination from photometric redshift errors means we cannot say for sure that galaxies in our high-density bin are quenched truly as a result of the environment which they live in. We therefore caution that the results found here are tentative but, due to the unique environmental information available in the UDS across such a large area and redshift range, are a first step in understanding the links between environment and quenching.

4.4 Low stellar mass galaxies in high densities

Conselice (2002), Penny & Conselice (2008), Vulcani et al. (2011) and Vulcani et al. (2013) explored the local galaxy SMF and luminosity function with respect to environment. These studies do not agree as to whether low stellar mass galaxies (or faint galaxies) are more abundant in high densities (i.e. do high densities form low stellar mass galaxies faster when considering the total galaxy population). There is no excess of low stellar mass galaxies at high densities in our results, which suggests this environmental effect is not present. This is the case at all redshifts. To explore this further would require a deeper data set to more accurately determine α .

To test how different definitions of high and low density may impact our results, the division between high and low density was altered in several ways. First, the same selection method as previously described was used, but with respect to $\log \rho$, rather than ρ , so that the distribution of densities is closer to being Gaussian. Secondly, galaxies were selected in the upper and lower 16 per cent of the distribution so that each density bin contained the same number of galaxies, and finally a constant density cut in each redshift range was tested. For the constant density cut we used the mean and standard deviation of the densities of all galaxies at all redshifts, rather than in separate redshift bins as in Fig. 8. Varying our definition of density in these ways had no impact on our results. We keep in mind a cautionary note regarding possible contamination between the high- and low-density bins. It is possible that similarities between the two SMFs are a result of the difficulties in clearly defining environment and improved photometric redshifts from future surveys will provide a clearer insight into this in the future.

5 SUMMARY

Using a combination of the UDS, CANDELS UDS and CANDELS GOODS-S data sets, the galaxy SMF for the total galaxy population over the redshift range $0.3 < z < 3.0$ is constructed. These data sets provide a combination of extremely deep near IR data and excellent

number statistics. Each of the data sets used here give us the power to accurately probe different parts of the galaxy SMF, as well as the galaxy SMF with respect to different galaxy properties. We take advantage of the environment information available in the UDS to investigate how the form of the SMF is affected by environment. Also utilizing the high-resolution imaging available in the C-UDS and GOODS-S fields, the galaxy SMF with respect to both Sérsic index and asymmetry is explored.

The major results of this paper are as follows.

- (i) We find that from low to high redshift, the faint end slope becomes steeper, M^* remains roughly constant, and ϕ^* is declining.
- (ii) The SMFs of galaxies in high and low densities are very similar, with the exception of massive galaxies living in denser environments at redshifts of $z < 1.5$.
- (iii) The impact of environmental processes on the shape of the galaxy SMFs of quenched galaxies is tested and we find tentative evidence for α being steeper in higher densities at $0.5 < z < 1.5$. The value of M^* is higher for red systems in high density which suggests high density is causing more efficient growth of massive, quenched galaxies.
- (iv) Results from the literature are confirmed regarding the double Schechter function nature of both the total and quenched SMFs. In addition, we find that the form of the galaxy SMF of galaxies with $n > 2.5$ is best described as a double Schechter function at $z < 2$. This suggests mass dependant evolution of these galaxies.
- (v) The double Schechter function form of the $n > 2.5$ SMF is due to a combination of a quenched (red) high stellar mass population, and a star-forming (blue) low-mass population. This suggests that links between growth of a bulge and the cessation of SF are only present at the high-mass end.

If we are to understand the growth of galaxy stellar mass then the form of the galaxy SMF with respect to different properties needs to be understood. To advance in this field larger data sets are needed to improve the number statistics and reduce the uncertainties when computing number densities in subpopulations. Furthermore, higher resolution images are necessary to look at galaxy structure and future telescopes such as the James Webb Space Telescope, *Euclid* and the European Extremely Large Telescope will provide the quality of data required to advance these studies.
