ABSTRACT

X-ray observations of active galactic nuclei (AGNs) show variability on time-scales ranging from a few hours up to a few days. Some of this variability may be associated with occultation events by clouds in the broad-line region. In this work, we aim to model the spectral and polarization variability arising from X-ray obscuration events, serving as probes of the relativistic effects that dominate the emission from the innermost regions. We show that asymmetries can be clearly detected in the AGNs spectra as the cloud is shading different parts of the accretion disc. We also show that these effects can be detected in the temporal evolution of the polarization degree (P) and the polarization position angle (Ψ). The variations in P and Ψ are highly dependent on the inclination of the system, the position of the primary source and its intrinsic polarization. Considering the disc-corona system only, for an inclination $\theta = 30^\circ$ (60°), P increases up to ~ 20 per cent (30 per cent) in the 4–8 keV band, when the unpolarized primary source is obscured. However, after accounting for the contribution of parsec-scale material scattering the light in our line of sight (narrow-line region and molecular torus), the variability is smoothed out and the polarization degree can be reduced down to ~ 1 per cent (2 per cent). Our results suggest that the study of eclipses in AGNs with the next generation of X-ray spectral and polarimetric missions could provide unique information on the physics and structure of the innermost regions as well as of the parsec-scale material.

Key words: polarization – radiative transfer – relativistic processes – scattering – galaxies: active – X-rays: general.

1 INTRODUCTION

Active galactic nuclei (AGNs) are considered to be among the best laboratories to test extreme gravity regimes. The central engine of AGNs, composed of a supermassive black hole (SMBH) and its viscous accretion disc (Pringle & Rees 1972; Shakura & Sunyaev 1973), is responsible for most of the observed, tremendous, bolometric luminosity. The X-rays are of particular interest as they are thought to be produced very close to the gravitational potential well and are imprinted with distinctive, strong signatures of special and general relativistic effects. The main X-ray spectral component of AGNs spectra (known as primary emission) is likely due to Compton up-scattering of seed thermal ultraviolet (UV) photons arising from the accretion disc (e.g. Lightman & White 1988; Haardt & Maraschi 1993). The primary emission spectrum is well described by a power law with a high-energy cutoff. The relativistic effects are imprinted in the so-called ‘reflection spectrum’, characterized by a

prominent iron K α line at ~ 6.4 keV (rest frame) and a strong broad excess in the emission with respect to the primary at ~ 20 – 30 keV known as ‘Compton hump’. The reflection component is due to re-processing of the primary emission by the accretion disc, which acts like a mirror, reflecting high-energy radiation rather than absorbing it (e.g. George & Fabian 1991). X-ray emission in AGNs is thus expected to be polarized thanks to the scattering processes happening in the vicinity of the accretion disc, in addition to the possible polarization of the primary emission itself (e.g. Chandrasekhar 1960; Angel 1969; Haardt & Matt 1993). Absorption and line re-emission also contribute to the total polarization by diluting the signal, adding to the spectrum several local depolarized features (Matt 1993). The polarization signal is strongly affected by 1) the geometry of the corona-disc system (e.g. Schnittman & Krolik 2009, 2010) and 2) general relativistic effects that parallelly transport the polarization position angle along the photon null geodesics (see e.g. Matt 1993; Dovčiak et al. 2008, 2011).

Several observational pieces of evidence confirmed the existence of a relativistically blurred reflection component in AGNs. In partic-

* E-mail: ekammoun@sissa.it

ular, X-ray spectroscopy has proven to be a powerful tool to identify the reflection features in AGNs X-ray spectra, allowing us to probe the innermost regions of AGNs (e.g. Fabian et al. 2009). Additionally, this technique may provide estimates of black hole spins (e.g. Risaliti et al. 2013; Marinucci et al. 2014; Walton et al. 2014). This was achieved thanks to the high-quality spectra provided by *XMM-Newton* (Jansen et al. 2001) and *NuSTAR* (Harrison et al. 2013) in the 0.3–80 keV range. The first observational X-ray feature associated with relativistic effects was the anomalous shape of the aforementioned iron K α line detected in type-1 AGNs, where the observer has a direct view of the central engine through the polar direction of the system (e.g. Matsuoka et al. 1990; Pounds et al. 1990). The shape of the iron line, with an extended red wing spanning over several keV was soon associated with special and general relativistic effects blurring the signal (e.g. Tanaka et al. 1995; Iwasawa et al. 1996; Nandra et al. 1997). By fitting the observed iron line with relativistic models, it became possible to determine the spin of the black hole (BH), its mass and inclination (see e.g. Miller 2007, for a review). Yet, an alternative interpretation, based on partial covering absorption, has been proposed in order to explain the apparent red wing of the Fe line and the spectral curvature at hard X-rays (e.g. Miller, Turner & Reeves 2008, 2009). The two scenarios have different advantages: on the one hand, blurred reflection is able to explain the spectral and timing properties of accreting systems for a wide range of BH mass. On the other hand, the Compton-thin to Compton-thick (and vice versa) rapid transitions that are observed in “changing-look” AGNs (Matt, Guainazzi & Maiolino 2003) is suggestive that partial covering should be also taken into consideration. In addition, several occultation events, associated with both Compton-thin and Compton-thick clouds in the broad-line region (BLR), have been reported in AGNs (e.g. Risaliti et al. 2007, ; Nardini & Risaliti 2011; Sanfrutos et al. 2013; Torricelli-Ciamponi et al. 2014). Markowitz, Krumpke & Nikutta (2014) estimated the probability to observe an X-ray eclipse (of any duration between 0.2 d and 16 yr) in a given source to be in the ranges 0.003–0.166 and 0.039–0.571, for type I and type II AGNs, respectively. By studying X-ray eclipses, it might be possible to constrain the importance of partial obscuration, together with the geometry and location of the distant obscuring clouds. This is particularly relevant since obscuration events from BLR clouds do not affect only the AGNs light curves but they show also a strong impact on their spectroscopic and polarimetric properties. Risaliti et al. (2011) investigated the effects of successive eclipses of the receding and approaching parts of the accretion disc on the shape of the iron line. In fact, due to special and general relativistic effects, obscuring various parts of the disc will result in a variability in the profile of the observed emission line, which provides a new probe of the innermost regions of the disc. In a similar fashion, Marin & Dovčiak (2015) explored the effects of such events on the polarimetric signal. The authors showed that eclipses induce a variability in the polarization signal due to the covering of different parts of the disc emitting a non-uniformly polarized light, mainly due to relativistic effects.

These pioneering studies predict what a time-resolved spectroscopic or polarimetric observation would detect, provided that the source is bright enough and that a random occultation event is serendipitously caught. Both the aforementioned papers considered a simple geometry for the accretion disc, divided in a receding and an approaching halves, illuminated by a power-law primary continuum. It is now possible to refine those studies by applying the state-of-the-art relativistic modelling to account for a more complex disc flux pattern, together with a better constrained coronal emission. In this work, we build upon the previous analyses by Risaliti

et al. (2011) and Marin & Dovčiak (2015) in order to estimate the spectral variability as well as the time-dependent polarization that are induced by obscuration events. In this paper, we use a full relativistic ray-tracing model that allows us to track the position of a spherical cloud as it obscures different regions of the disc. The disc is illuminated by a point-like source located on the axis of rotation of the BH, known as lamp-post geometry. We describe our model in Section 2 and present in Section 3, the spectroscopic signatures of various eclipsing events. We present in Section 4, the variability pattern induced by these events in the polarization signal. We show also, in the same section, how the polarization signal may be altered by accounting for a more complex and realistic AGNs model, namely by adding the contribution to polarization from the narrow-line region (NLR) and a molecular circumnuclear torus. We discuss the implications of our results in terms of observability in Section 5 and present our conclusions in Section 6.

2 MODEL

Our model consists of a central BH of mass $M_{\text{BH}} = 10^7 M_{\odot}$ that is accreting matter through an optically thick geometrically thin disc. This mass is typical for nearby Seyfert galaxies (see e.g. Lubiński et al. 2016). The disc is inclined by $\theta = 30^\circ$ or 60° with respect to our line of sight. We consider a Schwarzschild BH (i.e. with a dimensionless spin parameter of 0) and a maximally rotating Kerr BH (with spin 0.998). The primary source is assumed to be point-like (lamp post), located on the rotation axis of the BH, emitting a power-law spectrum with a photon index $\Gamma = 2$. We investigate in this work the effects of the height of the source by considering a source at heights 2.5, 6, and $10 r_g$ ($r_g = GM/c^2$). The higher the height, the weaker the gravitational redshift and the light-bending effect, which will lead to illuminating further out regions of the disc by the lamp post. The X-ray spectra are simulated using different flavours of the relativistic ray-tracing `KYN`¹ code (Dovčiak et al. 2014), which computes the time evolution of a local spectrum seen by a distant observer. The model allows us to consider obscuration by a spherical cloud, as it crosses the line of sight of the observer. The cloud is characterized by two numbers (α , β), which represent the position of the centre of the cloud on the sky of the observer (impact parameters of the centre) in the azimuth and altitude (φ , θ) direction, respectively, and by its radius R_c . We assume a cloud of radius $30 r_g$ that is moving with a Keplerian velocity (v_K), in the plane $\beta = 0$, and located at a distance of $10^4 r_g$ from the central BH (see e.g. Risaliti et al. 2009; Marinucci et al. 2014) moving from $\alpha > 0$ (the approaching part of the disc) toward $\alpha < 0$ (the receding part of the disc). This will result in a duration of the eclipse $\Delta t = 2R_c/v_K \simeq 295$ ks. This is in agreement with the duration of the eclipse in MCG–06–30–15 ($M_{\text{BH}} \simeq 1.6 \times 10^6 M_{\odot}$; Bentz et al. 2016), which was reported by McKernan & Yaqoob (1998), when scaled for the mass of the source. A scheme of the corona-disc-cloud system as projected in the observer’s sky is presented in Fig. 1.

3 SPECTRAL SIGNATURES

In this section, we compute the predicted spectral signatures of an X-ray eclipse by a Compton-thick cloud orbiting the BH. We assume the following model:

$$\text{model} = T \text{Babs} \times \text{KYNXillver}_{\text{abs.}} + \text{KYNXillver}_{\text{non-abs.}},$$

¹<https://projects.asu.cas.cz/stronggravity/kyn>

Figure 1. Scheme of the configuration which we propose in this work, depicting a spherical cloud moving along the line of sight and shading different parts of the accretion-disc and lamp-post (white dot) system. The colour scale represents the energy shift defined as the ratio observed energy over local energy ($g = E_o/E_l$). α and β represent the coordinates on the sky of the observer in units of r_g (impact parameters) in the $\varphi - \theta$ direction, respectively.

where TBabs (Wilms, Allen & McCray 2000) represents a spherical cloud of column density $N_H = 10^{24} \text{ cm}^{-2}$ (equivalent, for $R_C = 30 r_g$ and $M_{BH} = 10^7 M_\odot$, to a number density $\sim 10^{10} \text{ cm}^{-3}$, which is consistent with the expected values for the BLR clouds), while $KYNXillver_{abs.}$ and $KYNXillver_{non-abs.}$ represent the spectrum that is transmitted² through the cloud and the non-absorbed spectrum, respectively. The reprocessing of the primary emission in the ionized disc is estimated according to the XILLVERD tables (see García et al. 2016). We considered an ionized disc with density $n_H = 10^{15} \text{ cm}^{-3}$, ionization parameter $\log \xi_d = 2$, and solar abundance, observed at inclinations of $\theta = 30^\circ$ and 60° . Fig. 2 shows the resulting spectra for different positions of a cloud of radius $30 r_g$ as it passes in the line of sight for Schwarzschild and Kerr BHs (dashed red lines and solid blue lines, respectively) and lamp-post heights of $2.5, 6,$ and $10 r_g$, for $\theta = 60^\circ$. The spectral variability for the case of $\theta = 30^\circ$ shows a very similar trend compared to the 60° case.

A clear decrease in the flux below ~ 20 keV can be observed when the lamp post is obscured. The source becomes reflection dominated, since the main contribution is from the unobscured parts of the disc. Below 4 keV, the flux decreases on average by ~ 30 and 100 times, for $h = 10 r_g$ and $h = 2.5 r_g$, respectively. In the Fe line band (5–7 keV), we see a smaller decrease by a factor of ~ 7 –8, which is similar for all heights. By comparing positive and negative values of α , this figure clearly shows the asymmetry that is introduced by the relativistic effects as the cloud obscures different parts of the disc. When the cloud is obscuring the receding patches of the disc ($\alpha < 0$) the intensity is typically higher compared to its symmetric position when the cloud is obscuring the approaching patches of the disc ($\alpha > 0$).

We note that the differences in spectral shape and intensity between a BH of spin 0 and 0.998 are larger for lower heights. It is clear from the upper row of Fig. 2 that the spectra corresponding to the Kerr BH are brighter than the ones corresponding to a Schwarzschild BH. The difference in intensity for $h = 2.5 r_g$ is mainly due to the fact that, in the latter (Schwarzschild) case, the primary is much more diluted due to the source being very close to the event horizon (only distant $0.5 r_g$ as opposed to $1.5 r_g$ in the former, Kerr, case). Moreover, there is less reflection due to the fact that the innermost stable circular orbit is ~ 5 times farther from the BH. These differences become less prominent for larger heights as light bending gets weaker and the lamp post can illuminate further out regions of the accretion disc. This is in agreement with previous spectral analyses (e.g. Dovciak et al. 2014; Fabian et al. 2014; Kammoun, Nardini & Risaliti 2018)

We note also that the profiles of the emission lines differ when different parts of the accretion disc are shaded, as shown in Fig. 3. This figure presents a zoom-in on the observed spectra in the 3.5–8.5 keV band, which is dominated by the Fe K line, for the cases when the cloud is obscuring the approaching ($\alpha = +30 r_g$) and receding ($\alpha = -30 r_g$) parts of the disc. We considered the cases of Schwarzschild and Kerr BHs, for lamp posts at $h = 2.5$ and $6 r_g$ above the accretion disc with an inclination of 60° . In addition to the effects mentioned above, this figure clearly shows the variability in the profile of the Fe line owing to shading various regions of the accretion disc. When the cloud is obscuring the receding parts of the disc, the unobscured (approaching) parts of the disc will dominate the observed spectrum. In this case, the spectrum is brighter and the

²We note that we considered the photoelectric absorption only, neglecting Compton scattering out of and into the line of sight.

Figure 2. The observed spectra resulting from obscuration events as a clouds of radius $30 r_g$, located at a typical BLR radial distance and orbiting Schwarzschild ($a^* = 0$; dashed red lines) and Kerr ($a^* = 0.998$; solid blue lines) BHs, is passing through the observer's line of sight (i.e. for different values of α , assuming $\beta = 0$). We consider primary sources located at 2.5, 6, and $10 r_g$ above an accretion disc with an inclination of 60° .

Figure 3. The observed spectra, in the 3.5–8.5 keV range, considering a cloud of radius $30 r_g$ obscuring the approaching ($\alpha = 30 r_g$, solid red lines) and receding ($\alpha = -30 r_g$, dashed blue lines) parts of the accretion disc for BH spins of 0 (left-hand panels) and 0.998 (right-hand panels). We consider primary sources located at 2.5 and $6 r_g$ (top and bottom panels, respectively) above an accretion disc with an inclination of 60° .

emission line is blueshifted with respect to the case when the cloud is obscuring the approaching part of the disc, thanks to Doppler boosting and Doppler shift effects.

Moreover, our model allows us to estimate the time evolution of the hard-to-soft ratio (HR) light curves during eclipses. Fig. 4 shows examples of the HR light curves of the fluxes in the 4–8 keV band (characterized by the Fe K line) and the 10–30 keV band (characterized by the Compton hump) over the one in the 1–3 keV band (representing the primary emission) during the eclipse by a cloud of radius $30 r_g$. We consider the cases of a maximally rotating Kerr BH with a lamp post at $2.5 r_g$ and a Schwarzschild BH with a lamp post at $6 r_g$ above an accretion disc with an inclination of 60° . Considering the first case, the HRs are constant when the cloud is obscuring the outer parts of the disc. A small dip can be then observed for $\alpha \simeq 32 r_g$ as the cloud obscures the innermost regions of the disc, where Doppler boosting is maximum, leading to a decrease of the flux in the hard bands, where reflection from the disc is important. This dip is smaller for the 10–30 keV band, which will be affected less by absorption for the considered column density ($N_H = 10^{24} \text{ cm}^{-2}$). Once the primary source is obscured, the HRs increase suddenly due to the decrease of the flux in the 1–3 keV band. As the cloud moves into the line of sight, the HR increases until reaching $\alpha \simeq 1.5 r_g$ then starts decreasing again. We note that the HR plots show an asymmetric profile, due to relativistic effects as the cloud obscures different regions of the accretion disc. A qualitatively similar behaviour can be also observed for the

Figure 4. Examples of the hard-to-soft flux ratios expected from X-ray eclipses by a cloud of radius $30 r_g$, as it moves along the line of sight. We consider the soft band in the 1–3 keV range as a proxy of the primary emission, and two hard bands, the 4–8 (top panel) and 10–30 keV (bottom panel) bands, which should be dominated by the FeK line and the Compton hump, respectively. We show the cases of a maximally rotating BH with a lamp post located at $2.5 r_g$ (solid blue lines) and a Schwarzschild BH with a lamp post located at $6 r_g$ (dashed red lines).

case of $a^* = 0$ and $h = 6 r_g$. The main differences compared to the previous case are that 1) the obscuration of the primary occurs later due to the fact that the lamp post is at a larger height and 2) the dip at $\alpha \simeq 32 r_g$ is less prominent due to the fact that for low spins the disc does not extend close to the BH, thus the innermost regions which are supposed to be affected the most by relativistic effects do not contribute to the observed signal. HR light curves were also studied by Sanfrutos et al. (2016), who assumed instead a radially extended corona. We note that many AGNs, at low redshift, show large amplitude variability on time-scales of a few tens of kiloseconds. MCG–6-30-15, for example, showed an intensity change by a factor of ~ 4 within ~ 10 ks (e.g. Fabian et al. 2002). When this variability is caused by a change in the intrinsic luminosity of the primary with a constant power-law slope, the HR light curves are

expected to be constant. However, some sources may also reveal a variability in the power-law slope on time-scales of a few tens of kiloseconds, as it is the case for IRAS 13224–3809, which shows a positive correlation between the power-law slope and the brightness of the source, i.e. the brighter the source, the softer the power law (e.g. Kammoun, Papadakis & Sabra 2015; Jiang et al. 2018). A similar behaviour was observed on longer time-scales (~ 7 – 1 yr; e.g. Sobolewska & Papadakis 2009). For such variability scenario, the HR will be larger when the source is dimmer, showing a similar behaviour to the one expected from X-ray eclipses. However, the shape of the HR strongly depends on the variability pattern and such analysis is beyond the scope of this paper.

4 POLARIMETRIC SIGNATURES

In this section, we present the effects of obscuration events on the polarization signal. For this reason, we use the `KYN1pcr` model that allows us to obtain the STOKES parameters (I , Q , U , V), the polarization degree (P), and the polarization position angle (Ψ) as a function of energy (in the 2–60 keV range), for each position of the cloud. The polarization degree is computed according to the usual Stokes formalism, i.e.

$$P = \frac{\sqrt{Q^2 + U^2 + V^2}}{I}$$

and the polarization position angle is

$$\Psi = \frac{1}{2} \arctan\left(\frac{U}{Q}\right).$$

We define the polarization position angle with respect to the system rotation axis, so a value of 0° (90°) will be referred to as parallel (perpendicular) polarization. For this case, the model assumes a neutral accretion disc based on the NOAR tables (Dumont, Abrasart & Collin 2000), for spectral features of the disc reflection, with single scattering approximation (Chandrasekhar 1960) for local polarimetric properties. We note that reflection tables for the polarization of ionized discs are not available in the literature yet (Goosmann, Marin et al., in preparation). The effect of disc ionization would be imprinted mainly in the unpolarized emission lines characterizing the reflection component, affecting mainly the soft X-rays. The cloud is assumed to be optically thick ($N_H \rightarrow \infty$). In reality, the contribution of the transmitted light, through the cloud, to the polarization signal is negligible (see Marin & Dovčiak 2015), hence it can be safely neglected. We consider a primary source at heights 2.5, 6, and $10 r_g$, being either unpolarized or polarized with $(P, \Psi) = [(2 \text{ per cent}, 0^\circ), (2 \text{ per cent}, 90^\circ)]$. The real polarization state of the primary source depends on its geometry, properties (temperature and optical depth), and the viewing angle. Thus we chose these states as an intermediately polarized light, which is expected from a symmetric corona (see Schnittman & Krolik 2010, for more details). We considered both Schwarzschild and Kerr BHs and inclinations of 30° and 60° .

Fig. 5 shows two examples of the pattern of the polarized light throughout an accretion disc for the two considered inclinations, assuming a lamp post at $2.5 r_g$ above a Kerr BH. The zoomed-out snapshots (upper panels) show that the contribution to the polarized signal is mainly arising from the innermost regions of the accretion disc. Moreover, it is clear from these panels that, due to the asymmetry caused by the non-zero inclination, the contributions from the ‘equatorial’ regions of the disc are larger than the ones from the ‘polar’ zones. We note that this effect is higher for larger inclinations. This figure also shows the dependence of the polar-

Figure 5. The expected polarization, in the 2–8 keV range, throughout the accretion disc (projected in the observer’s sky) for a lamp post located at $2.5 r_g$ above a Kerr BH. We consider inclinations of 30° (left-hand panels) and 60° (right-hand panels). The black curves depict the direction of the polarization at the detector. It is determined by the local polarization direction induced by disc reflection (for an unpolarized primary) as well as the rotation of the polarization vector between the disc and observer due to relativistic effects. The colour scale represents the polarized flux (defined as total flux times polarization degree, in log scale). The lower panels show a zoomed-in snapshot of the innermost regions of the disc, where the relativistic effects dominate.

ization angle on the location of the emission from the disc. The polarization induced by the scattering process has a perpendicular direction to the scattering plane. Thus the polarization of the rays emitted from the on-axis primary source and scattered from the accretion disc at large radii, where both the special (due to relatively slower orbital speeds) and general relativistic effects (due to the smaller gravity) are weak, will depend only on the azimuth, which determines the scattering plane. For example, the light rays emitted towards or away from the observer that scatter from the accretion disc and reach the observer (polar regions of the accretion disc in Fig. 5, close to $\alpha = 0$) have a vertical plane of scattering, and thus the polarization direction is horizontal. On the other hand, the light rays emitted to the east or west side of the accretion disc that scatter towards the observer (equatorial regions of the accretion disc in Fig. 5, close to $\beta = 0$) have a horizontal scattering plane, and thus the polarization direction is vertical.

We also note the presence of a depolarizing region (a.k.a. ‘critical point’, see Dovčiak et al. 2008) located to the north-west of the BH ($\alpha > 0$ and $\beta > 0$ in Fig. 5), where the photons are emitted perpendicularly to the disc, due to special relativistic aberration. The location of this region depends on the spin of the BH and on the inclination angle, and it may get closer, or even within the ISCO in some cases (see fig. 3 in Dovčiak et al. 2008). Moving closer to the BH from the critical point, the relativistic effects are strong enough to affect the incident and reflection angle of the photons in the local comoving frame. Therefore, also the orientation of the local scattering plane and consequently of the polarization direction will be altered with respect to the cases where relativistic effects are

not as prominent. The polarization direction is further changed as the polarization vector is transferred from the inner accretion disc to the observer at infinity. Hence the observed direction of polarization from these regions is not trivial (see the central parts of the accretion disc in Fig. 5).

4.1 Energy dependence

We present in Fig. 6 the total flux, the polarized flux defined as the total flux times the polarization degree, the polarization degree, and the polarization position angle as a function of energy for unpolarized and polarized primary located at $2.5 r_g$ above the disc. We show the results for both Schwarzschild and Kerr BHs (top and bottom panels, respectively). We considered the cases of an unobscured source and the case when the primary is obscured by a cloud ($R_c = 30 r_g$) in the line of sight aligned with the BH ($\alpha = 0 r_g$), as an example.

Considering the unobscured cases, we note that the higher the inclination the higher the polarization degree, due to special and general relativistic effects (Dovčiak et al. 2011). For the unpolarized and parallelly polarized primary, $P(E)$ increases with energy. At low energies photoabsorption in the disc dominates, thus $P(E)$ is the same as the one of the primary emission. However, for higher energies where the disc reflection becomes more important, the polarization varies (increases or decreases) depending on the polarization angle of the irradiating spectrum. Scattering inside the disc tends to result in parallel polarization angles. If the irradiating emission is parallelly polarized, then the resulting polarization degree increases. Otherwise, the orthogonality between the two vectorial components tends to decrease the net polarization degree. We note that, for the perpendicular polarization, at $\theta = 30^\circ$, the polarization degree shows a dip at energies below ~ 10 keV and 7 keV, for the Schwarzschild and Kerr BHs, respectively. Then it increases continuously at higher energies. A similar behaviour can be seen for $\theta = 60^\circ$ but the transition energies are ~ 7 and 4 keV, respectively. These transitions are accompanied by a decrease in the polarization position angle at higher energies, due to the fact that scattering inside the disc becomes more prominent at higher energies, resulting in parallel polarization angles. The energy at which the rotation occurs depends on the spin of the BH, which determines the location of the ISCO. The higher the spin, the closer the ISCO to the BH, which leads to a variation in Ψ at lower energies.

Considering the obscured spectra, which correspond to pure reflection, the polarization degree is boosted up to ~ 15 per cent and ~ 38 per cent for $\theta = 30^\circ$ and 60° respectively. This is due to the obscuration of the primary emission, being either unpolarized or slightly polarized but with a high flux, which tends to dilute the polarization signal from the disc. The $P(E)$ patterns show a clear decrease in polarization due to the broad emission lines from the disc, which are expected to be unpolarized (e.g. Matt 1993). Fig. 6 shows a decrease in the polarization position angle for all cases. We stress that the behaviours of $P(E)$ and $\Psi(E)$ are highly dependent on the position of the cloud as it eclipses different parts of the accretion disc, as we will discuss in the next section.

4.2 Time dependence

We explore in this section the variability (on a time-scale up to a few hundred ks) that is introduced in the polarization signal due to obscuration events. Figs 7–9 show the temporal evolution of the flux, the polarization degree, and polarization position angle as a cloud of radius $30 r_g$ eclipses the innermost parts of an AGNs.

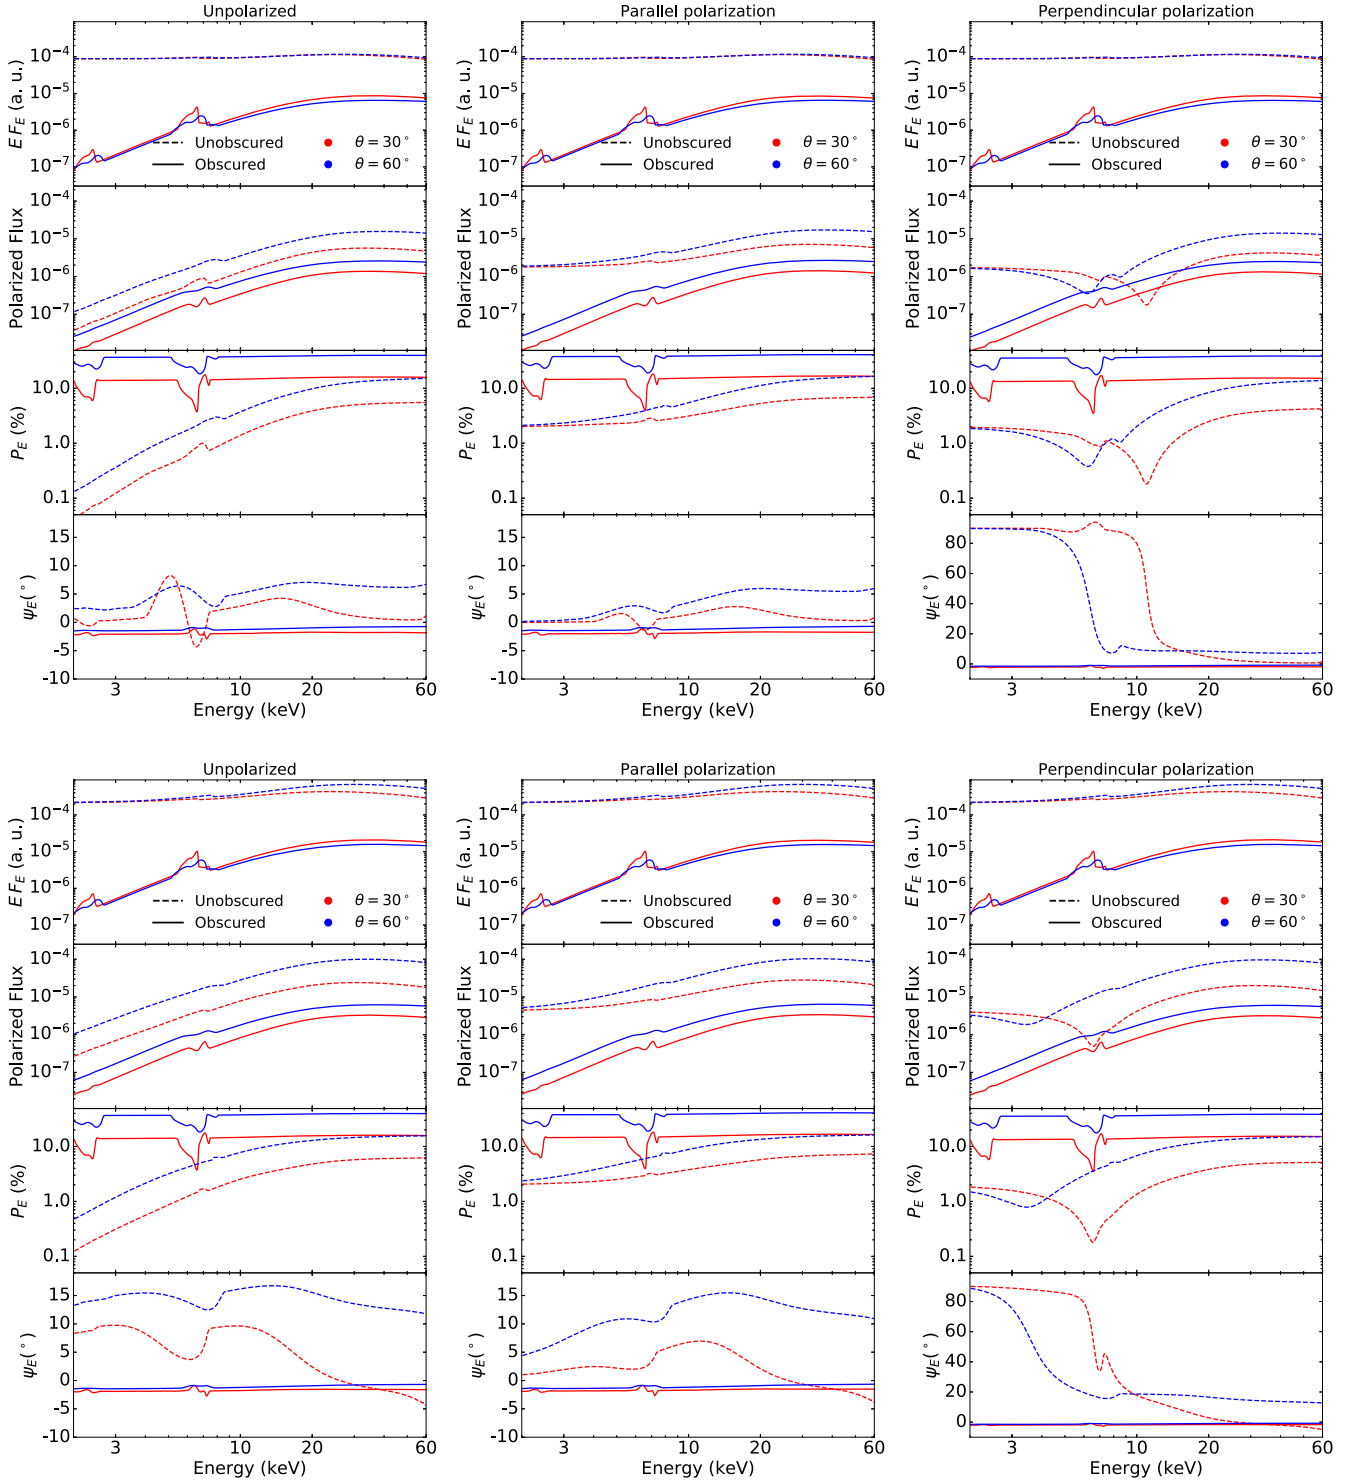

Figure 6. X-ray flux (EF_E), polarized flux (EF_E times the polarization degree), polarization degree P , and polarization position angle Ψ as function of energy seen by an observer at infinity. We consider a point-source corona at $2.5 r_g$ above the BH spinning with $a^* = 0$ (top panels) and $a^* = 0.998$ (bottom panels) with an accretion disc that is inclined by 30° (red lines) and 60° (blue lines). The parameters are shown for two configurations: an unobscured system (dashed lines) and a system that is obscured by a cloud, of radius $30 r_g$, that is aligned with the BH.

We present in Fig. 7 the results, assuming an unpolarized primary located at $2.5 r_g$ above either a Schwarzschild or a Kerr BH, for inclinations of 30° and 60° . In Figs 8 and 9, we present the same results for a 2 percent (parallelly and perpendicularly, respectively) polarized primary. We considered four energy bands: 2–4, 4–8, 8–

20, and 20–50 keV. The polarization signal of the accretion disc is not uniform due to relativistic effects (see e.g. Schnittman & Krolik 2009, 2010), as shown in Fig. 5. Thus the variability pattern seen in these figures is caused by receiving signal from differ-

Figure 7. Temporal evolution of the X-ray flux, polarization degree (P), and polarization position angle (Ψ) in the 2–4 keV, 4–8 keV, 8–20 keV, and 20–50 keV bands. We considered accretion discs with inclinations of 30° (top panel) and 60° (bottom panel) around Schwarzschild (red lines) and maximally Kerr (blue lines) BHs. We considered an optically thick cloud ($R_c = 30r_g$) eclipsing the system whose primary ($h = 2.5r_g$) is unpolarized.

ent patches of the disc as the cloud is moving across the line of sight.

We consider first the unpolarized primary case for an inclination of 30° . In the 2–4 keV band, the polarization degree starts from a negligible value in the unobscured case then it shows a small increase, followed by a decrease, as the cloud is moving closer to the centre ($\alpha \simeq 36$ and $32 r_g$ for the Schwarzschild and Kerr BHs, respectively) that is accompanied by a little decrease in flux and a remarkable variation in polarization position angle. This effect is mainly due to the obscuration of the depolarizing region located to the north-west of the BH (see Fig. 5). We note that this effect is smaller for higher inclinations and/or low spin values since, in these cases, this region is very close to the horizon. As the cloud moves further it eclipses the lamp post causing the flux to drop drastically and increasing P , which reaches ~ 25 per cent (at $\alpha \simeq 23 r_g$) and

26 per cent (at $\alpha \simeq 25 r_g$) for Schwarzschild and Kerr BHs, respectively. However, Ψ rotates to negative values of $\sim -25^\circ$ and $\sim -50^\circ$ for Schwarzschild and Kerr BHs, respectively. $P(t)$ decreases with time and reaches ~ 12 per cent at $\alpha = 0 r_g$, for both spins, while $\Psi(t)$ increases up to $\sim -1^\circ$. As the cloud is moving away from the centre, $P(t)$ increases again up to ~ 16 per cent at $\alpha \simeq -23 r_g$ and $-25 r_g$ for Schwarzschild and Kerr BHs, respectively. This is accompanied by a decrease in $\Psi(t)$. As the cloud is moving further out and uncovering the lamp post, $P(t)$ decreases and re-increases suddenly at $\alpha \simeq -30 r_g$ ($\Delta P \simeq 2$ per cent and 6.7 per cent for Schwarzschild and Kerr BHs, respectively). As for $\Psi(t)$, its behaviour is inverted for the Kerr BH, while it increases continuously for the Schwarzschild case. This effect is due to unobscuring the depolarizing region described above. We also note that the approaching part of the disc contributes substantially to the polarization degree due to Doppler

Figure 8. Same as Fig. 7 but considering a 2 per cent parallelly polarized primary.

boosting (as shown in Fig. 5). This effect becomes more important for higher inclinations. Therefore, obscuring/unobscuring this part of the disc will lead to a decrease/increase in $P(t)$ before obscuring/unobscuring the primary source. As the cloud is moving out of the line of sight all the quantities go back smoothly to their original values. Qualitatively, a similar variability pattern can be seen for all energy bands, having different values as various processes and spectral features dominate in different energy bands. For example, the increase in polarization degree is the smallest in the 4–8 keV band, which is affected by the presence of the broad unpolarized Fe line. In general, the variation of $P(t)$ can be described by an asymmetric double peaked profile, where the peaks correspond to the start and the end of the eclipse, being larger for the former case. However, we note that this is inverted for the 20–50 keV band where the second peak is higher. We note that $P(t)$ and $\Psi(t)$ show a

qualitatively similar behaviour for the parallelly polarized primary as well.

For a perpendicularly polarized primary, $P(t)$ shows a similar behaviour compared to the other two cases. However, $\Psi(t)$ in the 2–4 keV and 4–8 keV bands starts from $\sim 90^\circ$ when the lamp post is unobscured then rotates quickly to negative values as soon as the primary is obscured, showing then a variability pattern similar to the parallelly polarized and unpolarized primary. $\Psi(t)$ then increases again to $\sim 90^\circ$ when the cloud is moving away from the line of sight. However, at higher energies, where scattering in the disc is more prominent, leading to a more parallel polarization, $\Psi(t)$ varies in a similar fashion to the previous polarization scenarios. We note that in all cases, both Schwarzschild and Kerr BHs show the same pattern when the innermost regions of the disc are obscured, while the patterns differ once these regions are unobscured. This is due to the fact that in the case of a Kerr BH the accretion disc reaches lower

Figure 9. Same as Fig. 7 but considering a 2 per cent perpendicularly polarized primary.

radii with respect to a Schwarzschild BH giving different observed polarization states.

We consider now the case of a higher inclination of $\theta = 60^\circ$. $P(t)$ varies in a similar way to the $\theta = 30^\circ$ case described above. However, we note that on the one hand it reaches higher values during obscuration, ~ 40 per cent. On the other hand, the double peaked features are smoother. As for $\Psi(t)$, we note that the differences between the Schwarzschild and Kerr BHs, for the uncovered primary, are bigger compared to the case of $\theta = 30^\circ$, being $\sim 2^\circ$ and 15° , respectively, in the 2–4 keV band (unpolarized and parallelly polarized scenarios). Then Ψ drops to lower values as the primary source is covered and rises again while the cloud is moving towards the receding part of the disc, to reach its initial value when the cloud moves away from the line of sight. Similarly to the lower inclination case, when the source is not obscured, $\Psi(t)$ is larger for energies below 8 keV compared to the one at higher energies.

4.3 Effects of the lamp-post height and the cloud radius

We investigate in Fig. 10 the effects of the height of the primary as well as the size of the cloud on the polarization signal. This figure shows the temporal variability in the 4–8 keV range for a non-rotating and a maximally rotating Kerr BH (top and bottom panels, respectively), for an unpolarized primary source located at 2.5, 6, and $10r_g$ above the disc ($\theta = 30^\circ$). We considered cloud radii of 5, 30, and $100r_g$ (for $N_H = 10^{24} \text{ cm}^{-2}$, the number density of the clouds will be $\sim 10^{11}$, 10^{10} , and 10^9 cm^{-3} , respectively, covering the whole range of BLR cloud densities). The first immediate difference between the various cloud sizes is the duration of the eclipse which is proportional to the cloud radius.

For $R_C = 5r_g$, the obscured regions of the disc are smaller than the other cases. We note that the eclipse occurs earlier when the source is at $2.5r_g$ compared to the $6r_g$ case. For these two cases, the variations of $P(t)$ while the cloud is moving within the line of

Figure 10. Temporal variability of the flux, polarization degree (P) and polarization position angle (Ψ) in the 4–8 keV band for an unpolarized primary at $h = 2.5 r_g$ (solid blue lines), $h = 6 r_g$ (dashed red lines) and $h = 10 r_g$ (dotted black lines), assuming a BH with $a^* = 0, 0.998$ (top and bottom panels, respectively) and an inclination $\theta = 30^\circ$. We considered a cloud of radii 5, 30, and $100 r_g$ (left, middle, and right columns, respectively).

sight are smoother for $a^* = 0$. This is due to the fact that the disc does not extend down to the regions, shaded by the cloud, where the effects should be the most intense. However, a larger gradual and asymmetric variability of Ψ is expected, during the motion of the cloud, being $\sim 35^\circ$ for $\alpha = 10 r_g$ and decreasing to 1° when the cloud is eclipsing the source, then rising up to $\sim 18^\circ$ for $\alpha = -10 r_g$, for $h = 2.5 r_g$. More features are expected for the rotating BH case, especially for $h = 2.5 r_g$ as the ISCO shrinks to lower radii. In these cases, $P(t)$ and $\Psi(t)$ show more variability for low heights. We note that for $a^* = 0.998$, $P(t) \simeq 1$ per cent for the unobscured-primary case while it is ~ 0.3 per cent for $a^* = 0$. For $h = 10 r_g$, despite the fact that the source is not eclipsed at all some small variations are still expected in the polarization signal due to the obscuration of various parts of the accretion disc.

As for $R_C = 30$ and $100 r_g$, $P(t)$ shows qualitatively a similar variability pattern for the various heights, which is also consistent with

the one described in Section 4.2. However, the patterns get smoother and flatter for larger heights, during the eclipse event. We also note that the polarization degree is higher for lower lamp-post heights, as already discussed by Dovčiak et al. (2011). In fact, during the unobscured phases $P(t) \simeq 1.2$ per cent, 0.7 per cent, and 0.5 per cent for $h = 2.5, 6$, and $10 r_g$, respectively. Once the primary is obscured, these values reach a maximum of ~ 21 per cent, 13.5 per cent, and 10 per cent, respectively, for $R_C = 30 r_g$ and $a^* = 0.998$. The difference in $P(t)$ for different heights is smaller for the Schwarzschild BH case, $P(t) \simeq 0.6$ per cent for $h = 2.5$, and $6 r_g$ and 0.4 per cent for $h = 10 r_g$. $\Psi(t)$ shows a similar variability pattern for the three heights, however the transitions (rise/decay) are more gradual at larger heights (when $\alpha \gtrsim 30, 100 r_g$, for $R_C = 30$ and $100 r_g$, respectively). Instead, for larger heights, $\Psi(t)$ reaches higher values at the beginning of the eclipse, being $\sim 42^\circ, 60^\circ$, and 90° for $h = 2.5, 6$, and $10 r_g$, respectively at $\alpha \simeq 35 r_g$, for $R_C = 30 r_g$.

4.4 Effects of parsec-scale material

In practice the central SMBH, its accretion disc and corona are not isolated from the other AGNs components. The impact of absorption, re-emission, and scattering of parsec-scale structures has been explored in detail for spectroscopic and photometric purposes (see e.g. Ghisellini, Haardt & Matt 1994). Higher torus hydrogen column density will impact on the Compton hump (Murphy & Yaqoob 2009, 2011). The impact of additional reprocessing from parsec-scale AGNs structures on the X-ray polarization signal from type-1 AGNs has been neglected until recently. In Marin, Dovčiak & Kammoun (2018b), the authors investigate the differences between an isolated central engine and a real type-1 AGNs, accounting for biconical NLR and an equatorial obscuring region. Among the main conclusions, it was found that additional parsec-scale scattering increases the expected polarization degree by 0.5–1 percentage points in the case of an unpolarized or a parallelly polarized continuum source. Changes are more profound for a perpendicularly polarized primary.

In order to create a more physical model of X-ray eclipses, we decided to also account for a more realistic geometrical scheme. In addition to the hot corona and the accretion disc, we consider the contribution of an additional equatorial molecular torus and a biconical NLR to the observed polarized light that is scattered along the observer's line of sight, using the STOKES code.³ STOKES is a Monte Carlo code developed by Goosmann & Gaskell (2007), Marin et al. (2012b), Marin, Goosmann & Gaskell (2015) and Rojas Lobos et al. (2018) that allows us to simulate the radiative transfer of photons in a wide three-dimensional environment. The code accounts for all the physics of scattering, absorption, and re-emission from the near-infrared to the hard X-ray band (with the exception of magnetically driven mechanisms such as synchrotron emission or dichroism that are not relevant here). Similarly to the work carried out by Marin et al. (2018a,b), it is possible to use the output from the KY code as input for STOKES. The photons can then propagate in a parsec-scale environment, allowing for a realistic radiative coupling between the central engine and the parsec-scale AGNs structure. In this case, we followed the work of Marin et al. (2018a,b) for Seyferts and included a circumnuclear torus with a half-opening angle of 30° from the equatorial plane and a hydrogen column density of 10^{24} cm^{-2} . The inner radius of the torus is set to a distance of 0.01 pc according to reverberation mapping data (Suganuma et al. 2006; Vazquez et al. 2015), and the outer one to 5 pc. The NLR is bi-conical, optically thin, and have a hydrogen column density of 10^{21} cm^{-2} . They represent the typical NLR detected in many AGNs and extend up to 60 parsecs before mixing with the galactic environment.

We present in Fig. 11, the temporal variations of the polarization parameters that include the extra contributions of the torus and the NLR, in the 4–8 keV and 20–50 keV bands. We also plot the parameters for the same configurations considering only the cloud-corona-disc system, for comparison. We considered only the case of unpolarized primary at $h = 2.5 r_g$. First, we note that, for all cases, the inclusion of the contribution from the torus and NLR results in an enhancement in the relative observed intensity during the eclipse. In fact, the contribution of these components to the scattered light in the line of sight is constant for the whole event and not affected by the eclipse itself. As expected, in the unobscured cases, the polarization degree increases when the contributions from the torus and NLR are

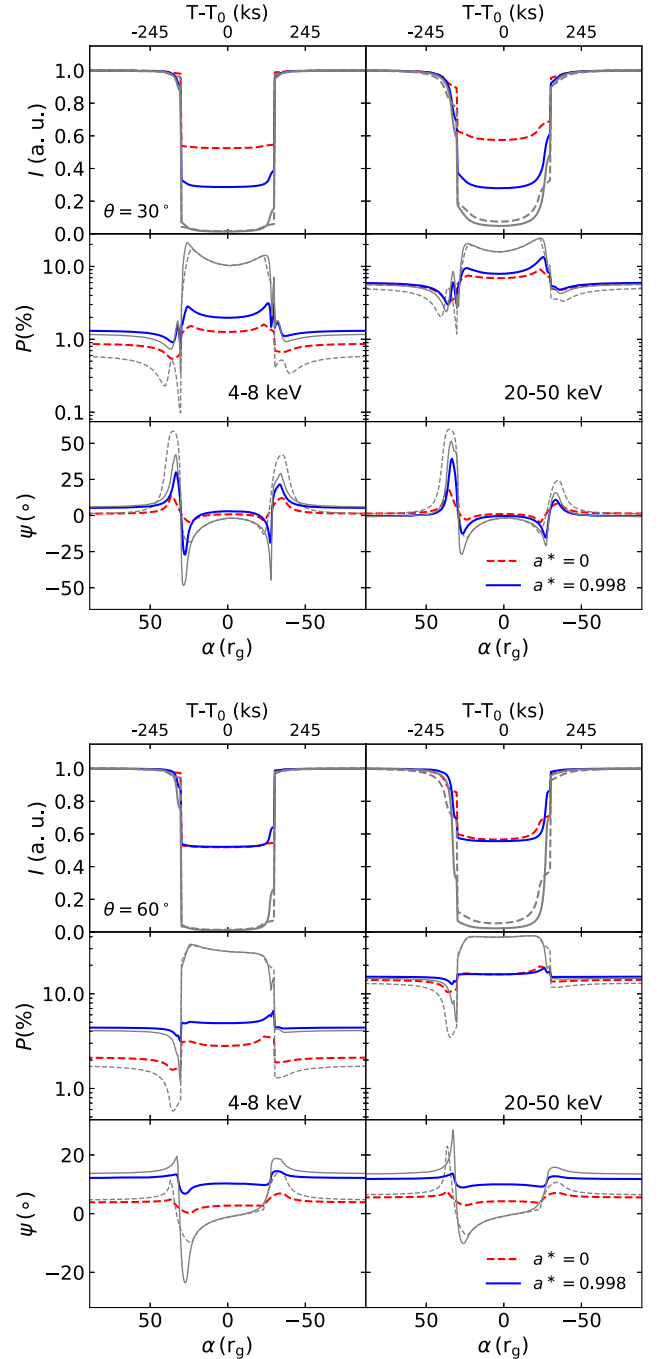

Figure 11. Similar to Fig. 7 but for 4–8 keV and 20–50 keV ranges only, taking into account the contribution from the bi-conical narrow line regions and molecular torus for inclinations of 30° (top panel) and 60° (bottom panel), for Schwarzschild (dashed lines) and Kerr (solid lines) BHs. The grey lines represent the temporal variations of the polarization degree and polarization position angle without including the effects of the NLR and molecular torus.

included, especially for higher energies. The inclusion of torus and NLR result in a small increase in $P(E)$ during the unobscured phase. This is in agreement with the results in Marin et al. (2018a,b) where the authors investigate the effect of the molecular torus and NLR on the polarization signal for type-2 and type-1 Seyferts, respectively. However, this contribution, being stable and non-negligible in terms of intensity, reduces the amplitude of variability, once the

³<http://stokes-program.info/>

primary is obscured. In fact, adding this contribution significantly dilutes the polarization signal leading to lower polarization degrees with respect to the cases when we do not account for these components, thus lower variability amplitude. During the eclipse, $P(t)$ becomes $\sim 1.3/2$ per cent (7/8 per cent) for the Schwarzschild/Kerr BHs in the 4–8 keV (20–50 keV) energy bands for an inclination of 30° . While for an inclination of 60° , $P(t)$ becomes $\sim 3/5$ per cent for the Schwarzschild/Kerr BHs in the 4–8 keV band, while it is ~ 16 per cent in the 20–50 keV for both spins. We note, however, that qualitatively the same variability pattern can be observed with and without the inclusion of the contribution from the parsec-scale material. The same is seen when comparing the variability patterns of $\Psi(t)$, with the only difference that the inclusion of the torus and NLR tends to reduce the values of the polarization position angles, leading to a more parallel polarization.

5 DISCUSSION

We showed that X-ray eclipsing events can be used in order to probe the emission from the innermost regions of AGNs. This had been investigated earlier by Risaliti et al. (2011), Marin & Dovčiak (2015) and Sanfrutos et al. (2016). However, we present in this work a new analysis taking into account full relativistic effects and more complex and physical configurations compared to the ones assumed in the aforementioned works. We note that our results depend on several uncertainties, mainly caused by our poor knowledge of the exact geometry of the system.

(i) An extended corona would be a more realistic case, and may lead to different spectral and polarimetric signatures with respect to the lamp-post geometry that is assumed in this work. This would mainly dilute the sudden changes caused by the high-compactness of the lamp post. One would expect to observe more gradual patterns during the obscuration of the primary (see e.g. Sanfrutos et al. 2016). However, we note that models with such a geometry are still not available for X-ray polarization.

(ii) The primary emission, assumed to be a power-law spectrum, is also expected to vary in flux and/or shape during the observation, which we do not take into consideration in this work.

(iii) The structure and geometry of the obscuring material may be more complex having a gradient of column density along the line of sight and a non-spherical shape (Maiolino et al. 2010). We also note that the column density of the obscuring cloud may play a role in modifying mainly the spectral signatures. Obscuration caused by clouds with lower column densities, on the order of $\sim 10^{23} \text{ cm}^{-2}$ (e.g. Risaliti et al. 2009; Maiolino et al. 2010), will mostly affect the soft X-rays.

Our spectral simulations are promising for the future high-resolution X-ray micro-calorimeters on board of ATHENA (Nandra et al. 2013) and, possibly, earlier X-ray missions such as Arcus (Smith et al. 2016) and XARM. The spectra that will be provided by the micro-calorimeters would be of great help in order to track the variability of fine spectral structures (especially the Fe line or the soft bands), during the eclipsing event. This would give us strong hints on the local emissivity of the disc, thus on the geometry of the corona. The detectability of these events and their implications will be investigated in future work. However, we note that it is not yet plausible to detect the effects of obscuration on the polarimetric signals in AGNs, on short time-scales. In fact, Marin et al. (2012a) showed that more than ~ 1 Ms will be needed for a XIPE-like S-class mission assuming a non-variable source with a flux of 3 mCrab in the 2–10 keV band. This is much larger than the time-scale of the

obscuration event in which the flux drops drastically, making the measurements even harder to be achieved. Instead, it would be possible with the up-coming X-ray polarimeters such as eXTP (Zhang et al. 2016) to catch changing-look (on larger time-scales) sources in two different obscured/unobscured states. Sources with high mass and/or large obscuring clouds would be optimal for such analysis, as the duration of the eclipse would be longer in these cases. Combining the spectral and polarimetric capabilities of future missions would allow us not only to probe the innermost regions of the AGNs, but it may give us also strong hints about the structure of the parsec-scale material. Our results clearly show that taking into consideration the contribution from this scattering material would alter the polarization signal in terms of polarization degree and position angle, as well as variability. These effects strongly depend on the structure and the geometry of the parsec-scale material.

6 CONCLUSIONS

We have shown in this paper how X-ray eclipses in AGNs can affect the observed spectral and polarimetric signals, being then a powerful means to probe the relativistic effects that dominate the innermost regions of these sources. Our main conclusions are the following:

(i) The observed X-ray spectra show asymmetries during the different phases of the eclipse as the cloud is shading various parts of the accretion disc. These effects depend strongly on the location of the primary source and the size of the obscuring cloud. We also showed that for large heights it becomes harder to determine the BH spin.

(ii) Considering the corona-disc system only, an asymmetric enhancement in the polarization signal is expected to occur as the cloud is shading the innermost regions of the system. This enhancement is highly dependent on the inclination of the system: the higher the inclination, the larger the polarization degree. In addition, the variability patterns of the polarization degree and the polarization position angle depend strongly on the location of the primary. We also showed that the effect of the spin is less prominent. However, the temporal evolution of the polarization position angle is highly affected by the intrinsic polarization of the primary source.

(iii) It is crucial to consider a full geometrical configuration of the AGNs. Accounting for the polarization signal from parsec-scale AGNs components, the expected total polarization from the whole system is strongly altered. The inclusion of the constant scattered light by the torus and NLR in the line of sight tends to increase the degree of polarization when the innermost regions are unobscured. However, once the corona is obscured, the contribution from the torus and NLR, which is not affected by the eclipsing event, tends to smooth out the variability in polarization. This reduces remarkably the degree of polarization, and leads to a more parallel polarization (Ψ closer to 0). We note that, despite the fact that in this case the variability of the polarization signal is lower, its absolute value can provide unique information on the geometry and the properties of the parsec-scale scattering medium.

In the future, we will investigate in more detail the observational prospects of spectral variability caused by obscuration events that will be detected by the next generation of X-ray observatories. We also aim at considering more realistic and complex configurations of the AGNs. Moreover, it is of particular interest to consider the impact of an extended corona on the observed spectral and polarimetric signatures, such as recently demonstrated by Chauvin

et al. (2018). Finally, we will also look at the effects of varying the characteristics of the accretion disc.

ACKNOWLEDGEMENTS

We are grateful to Dr. Giovanni Miniutti for providing valuable comments and suggestions that improved the manuscript. ESK acknowledges the support by the ERASMUS+ Programme – Student Mobility for Traineeship-Project KTEU-ET (Key to Europe Erasmus Traineeship). ESK thanks the Astronomical Institute of the Czech Academy of Sciences for hospitality during the early phase of this work. FM is grateful to the Centre national d'études spatiales (CNES) which provided research funding through the post-doctoral grant “Probing the geometry and physics of active galactic nuclei with ultraviolet and X-ray polarized radiative transfer”. MD thanks MEYS of Czech Republic for the support through the 18-00533S project. EN received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement no. 664931.
