ABSTRACT

We report results from an intensive multiwavelength campaign on the intermediate-frequency-peaked BL Lacertae object W Com ($z=0.102$) during a strong outburst of very high energy gamma-ray emission in June 2008. The very high energy gamma-ray signal was detected by VERITAS on 2008 June 7-8 with a flux $F(> 200 \text{ GeV}) = (5.7 \pm 0.6) \times 10^{-11} \text{ cm}^{-2}\text{s}^{-1}$, about three times brighter than during the discovery of gamma-ray emission from W Com by VERITAS in 2008 March. The initial detection of this flare by VERITAS at energies above 200 GeV was followed by observations in high energy gamma-rays (AGILE, $E_\gamma \geq 100 \text{ MeV}$), and X-rays (Swift and XMM-Newton), and at UV, and ground-based optical and radio monitoring through the GASP-WEBT consortium and other observatories. Here we describe the multiwavelength data and derive the spectral energy distribution (SED) of the source from contemporaneous data taken throughout the flare.

1. Introduction

W Com (ON 231; $z = 0.102$) is a gamma-ray blazar classified as an intermediate-frequency-peaked BL Lac (IBL) object (Nieppola et al 2006), based on the locations of its low-energy synchrotron peak and high-energy peak in its spectral energy distribution (SED). The majority of the blazars detected at very high energies (VHE, $E > 100$ GeV) by ground-based imaging atmospheric Cherenkov telescopes (IACTs) are high-frequency peaked BL Lacs (HBL), characterized by synchrotron peaks in the X-ray band (often at energies of ~ 100 keV). Due to the improved sensitivity of current-generation IACTs such as VERITAS, IBLs are attractive targets of observations at VHE gamma rays, particularly because they offer the possibility of extension of the VHE blazar catalog to include non-HBLs. VHE observations of different blazar classes, including flat-spectrum radio quasars (FSRQs) and BL Lac objects, will help in our understanding of the relationship of the different blazar populations and, ultimately, the mechanism for particle acceleration and emission in the highly-relativistic jets.

W Com was the first IBL to be detected at very high energies (Acciari et al 2008b). It was discovered as a VHE source by VERITAS during observations carried out over a four month period in 2008 (Jan to Apr). During this time a strong gamma-ray outburst was measured over a 4-day interval, when the source flared in the middle of March. VERITAS reported a steep photon spectrum ($\Gamma = 3.81 \pm 0.35_{\text{stat}} \pm 0.34_{\text{sys}}$)¹ and an integral flux of 9% of the Crab Nebula flux during the flare nights. The VERITAS detection triggered *Swift* observations, and the multiwavelength data obtained were adequately explained with a synchrotron-external Compton (EC) leptonic model (Acciari et al 2008b).

In this article we report on a second VHE flare in W Com observed by VERITAS in 2008 June. During this flare, when the source was approximately three times brighter than during the 2008 March observations, a multiwavelength campaign was triggered, including observations with the space-based AGILE gamma-ray telescope and the *Swift* and *XMM-Newton* X-ray telescopes. Here we describe the multiwavelength data and derive the spectral energy distribution (SED) of the source from contemporaneous data taken throughout the flare.

¹The subscripts *stat* and *sys* denote the statistical and systematic error.

2. Observations and Results

A summary of the complete multiwavelength data set on W Com for observation times close to the VHE detection on 2008 June 7-9 can be found in Table 1 and Figure 1.

2.1. VERITAS: VHE Gamma-ray observations

VERITAS is an array of four imaging Cherenkov telescopes located at the Fred Lawrence Whipple Observatory in southern Arizona. It combines a large effective area (up to 10^5 m²) over a wide energy range (100 GeV to 30 TeV) with good energy resolution (15-20%) and angular resolution ($\approx 0.1^\circ$). The field of view of the VERITAS telescopes is 3.5° . The high sensitivity of VERITAS allows the detection of sources with a flux of 1% of the Crab Nebula in less than 50 hours of observations. For more details on the VERITAS instrument, see Holder et al (2006) or Weekes et al (2002).

VERITAS observed W Com for 230 minutes on 2008 June 7-9. All observations pass quality-selection criteria, which remove data taken during bad weather or affected by hardware-related problems. The data were taken in wobble mode, wherein the source was positioned at a fixed offset of 0.5° in one of four directions (North, South, East, West) from the camera center. This allows the simultaneous estimate of the background (Fomin et al 1994). The regions around the VHE gamma-ray blazar 1ES 1218+304 (Acciari et al 2008c), located about 2° north of W Com, and around bright stars (B-band magnitude brighter than 6) are excluded from the background estimation. All observations were undertaken in moonlight conditions, where the elevated background light levels lead to a lower sensitivity for the detection of gamma rays at the threshold. The threshold of the first-level trigger system (Holder et al 2006) was increased to 70 mV (compared to a default value of 50 mV) to allow for very high background moonlight levels during observations on 2008 June 9. Table 2 lists observation times, elevation range, and background light conditions for the VERITAS observations. The different elevations of observation combined with the continuously changing background light conditions result in a range of energy thresholds from 200 to 420 GeV².

The analysis steps consist of calibration and integration of the flash-ADC traces, image cleaning, second-moment parameterization of the telescope images (Hillas 1985), stereoscopic reconstruction of the event impact position and direction, gamma-hadron separation (see e.g., Krawczynski et al. (2006)), and the generation of photon maps. Most of the far

² The energy threshold is defined as the energy at which the peak of the differential counting rate for a Crab Nebula-like spectrum occurs.

more numerous background events are rejected by comparing the parameterized shape of the event images in each telescope with the expected shapes of gamma-ray showers modeled by Monte Carlo simulations. *Mean-reduced-scaled width* and *mean-reduced-scaled length* cuts (see definition in Acciari et al (2008a)), and an additional cut on the arrival direction of the incoming gamma ray (Θ^2 , defined as the square of the angular distance to the position of W Com to the reconstructed shower direction), reject more than 99.9% of successfully reconstructed cosmic-ray background events while keeping 45% of the gamma rays. The cuts applied here are: integrated charge per image >75 photoelectrons, mean-reduced-scaled width and length between -1.2 and 0.5, and $\Theta^2 < 0.015 \text{ deg}^2$. The number of background events in the source region are estimated from the same field of view using the “reflected-region” model with 10 background regions (Aharonian et al 2001).

The energy of each event is estimated from detailed Monte Carlo simulations of extensive air showers and the response of the telescopes, focal plane detectors and electronics. The energy reconstruction algorithm uses lookup tables and determines the energy of an event as a function of impact parameter, integrated charge per image, background light level, offset of the arrival direction from the center of the camera, and zenith and azimuth angle. Gamma-ray collection areas for these different observing conditions are calculated using the same Monte Carlo simulations (Mohanty et al 1998). The finite energy resolution is taken into consideration by calculating collection areas as a function of reconstructed energy. The dependence of the collection area on the spectral index is taken into account by an iterative process, where collection areas are calculated using the spectral index obtained in the previous step. Convergence is usually achieved after 2-3 steps. The spectral reconstruction algorithm assigns to each event a collection area according to its estimated energy, background light level, offset of the arrival direction from the center of the camera, assumed spectral index, and zenith and azimuth angles. Varying conditions, like changing elevations or background light levels are therefore taken into account in the flux calculations and spectral energy reconstruction. It should be noted that the definition of energy threshold used here implies that collection areas are non-zero below the stated threshold value. Gamma rays are collected, although with lower efficiency, at energies well below 200 GeV even for the brightest background light levels. The systematic error in the estimation of the gamma-ray energy is dominated by variabilities and uncertainties in the atmospheric conditions, overall Cherenkov photon collection efficiency, and limitations of the Monte Carlo simulations.

Figure 2 shows the sky around W Com as seen by VERITAS in VHE gamma rays. A significant flux of very-high-energy gamma rays from W Com is detected by VERITAS for the entire data set taken on 2008 June 7-9. A total of 117 excess events (195 *on-source* events and 78 normalized *off-source* events, normalization factor of 0.10) are measured. This corresponds to a significance of 10.3 standard deviations, calculated following Equation 17

in Li & Ma (1983). Table 2 lists the daily significances and fluxes above 200 GeV, assuming a power-law like spectral shape with a photon index of 3.68 (see next paragraph); Figure 1 shows the light curve for these observations. W Com is not detected on 2008 June 9 (MJD 54626), but observations were restricted to only 32 min due to very high background light levels caused by the Moon. The average flux on 2008 June 7-8 is 2.5-3 times higher than during the gamma-ray flare from W Com in March 2008 (Acciari et al 2008b). The position of the peak of the gamma-ray excess, reconstructed by fitting a 2D-Gaussian function to the uncorrelated excess sky map, is in agreement with the position of the radio source associated with W Com (Fey et al 2004): $\Delta_{RA} = 40'' \pm 31''_{stat}$, $\Delta_{dec} = -55'' \pm 41.4''_{stat}$. The systematic uncertainty on the pointing, verified with optical pointing monitors, is less than $50''$. The morphology of the excess is compatible with the distribution expected from a point source.

The differential photon spectrum between 180 GeV and 3 TeV for the measurements from 2008 June 7-8 is shown in Figure 3. The shape of the spectrum is consistent with a power law $dN/dE = C \times (E/400 \text{ GeV})^{-\Gamma}$ with an photon index $\Gamma = 3.68 \pm 0.22_{stat} \pm 0.3_{sys}$ and a flux normalization constant $C = (6.5 \pm 0.9_{stat} \pm 1.3_{sys}) \times 10^{-11} \text{ cm}^{-2}\text{s}^{-1}\text{TeV}^{-1}$. For comparison, the flare in VHE gamma rays from W Com in 2008 March (Acciari et al 2008b) is well fit by a power law with a consistent $\Gamma = 3.81 \pm 0.35_{stat} \pm 0.34_{sys}$, but smaller flux constant $C = (2.00 \pm 0.31_{stat} \pm 0.5_{sys}) \times 10^{-11} \text{ cm}^{-2}\text{s}^{-1}\text{TeV}^{-1}$.

2.2. AGILE: HE Gamma-ray observations

The Gamma-Ray Imaging Detector (GRID, 30 MeV - 30 GeV) onboard the high energy astrophysics satellite AGILE (Tavani et al 2008a) pointed towards W Com continuously from 2008 June 9 (18:00 UT) to 15 (12:00 UT) (Verrecchia et al 2008). The GRID data is analyzed using the AGILE standard pipeline (Vercellone et al 2008), with a bin size of $0.25^\circ \times 0.25^\circ$. Only events flagged as gamma rays and not recorded while the satellite crossed the South Atlantic Anomaly are accepted. Events with reconstructed direction less than 10° of the Earth limb are rejected, thus reducing contamination from Earth's gamma-ray albedo. W Com was observed about 3 degrees off-axis with respect to the boresight and a 3.7σ excess (pre-trials) of events $>100 \text{ MeV}$ is found from 12 (03:00 UT) to 13 (03:00) June 2008, corresponding to a flux of $(90 \pm 32) \times 10^{-8} \text{ ph s}^{-1} \text{ cm}^{-2}$. It should be mentioned that this flux is roughly a factor of 1.5 higher than the highest flux detected by the Energetic Gamma Ray Experiment Telescope (EGRET; Hartman et al (1999)) onboard the Compton Gamma Ray Observatory and significantly higher than the weekly averaged peak flux of $(17.2 \pm 3.5) \times 10^{-8} \text{ ph s}^{-1} \text{ cm}^{-2}$ reported by the Large Area Telescope onboard the Fermi Gamma-Ray Space Telescope during its first three months of operation (Abdo et al 2009b).

No excess $> 3\sigma$ is found in the rest of the observing period and upper limits are obtained; results can be found in Table 3 and Figure 1.

SuperAGILE, the hard X-ray imager onboard AGILE (18-60 keV, Feroci et al (2007)) observed the source for a net exposure time of 253 ks. The source position in the orthogonal SuperAGILE reference system is $\sim (3,0)$ deg, which means that the exposed area is close to the full on-axis effective area (Feroci et al 2007). W Com is not been detected with SuperAGILE, and we estimate a 3σ upper limit in the 20-60 keV energy of 6 mCrab $\simeq 6.9 \times 10^{-11}$ erg cm $^{-2}$ s $^{-1}$ (assuming a photon index of $\Gamma = 2.1$).

2.3. *Swift* and *XMM-Newton*: X-ray observations

Observations of W Com with the *Swift* satellite (Gehrels et al 2004) were taken on 2008 June 7-9. All *Swift* X-ray telescope (XRT) data (Burrows et al 2005) are reduced using the HEASoft 6.5 package. Event files are calibrated and cleaned following the standard filtering criteria using the *xrtpipeline* task and applying the most recent Swift XRT calibration files. All data were taken in Photon Counting (PC) mode, with grades 0-12 selected over the energy range 0.3-10 keV. Due to photon pile-up in the core of the point spread function (PSF) at rates larger than 0.5 counts s $^{-1}$ (PC mode), the source events are extracted from an annular region with an inner radius of 3 pixels and an outer radius of 30 pixels (47.2 arcsec). Background counts are extracted from a 40 pixel radius circle in a source-free region. Ancillary response files are generated using the *xrtmkarf* task, with corrections applied for the PSF losses and CCD defects. The response matrix Version 11 from the XRT calibration files is applied. To ensure valid χ^2 minimization statistics during spectral fitting, the extracted XRT energy spectra are re-binned to contain a minimum of 20 counts in each bin. The spectra can be described by a single power-law convolved with galactic and local absorption. Table 4 summarizes the observations along with the best fit model parameters.

W Com was observed by the XMM-Newton Observatory (Jansen et al. 2001) between 2008 June 14 and June 18 over three consecutive orbits. The three observations comprise data from the EPIC detector (0.2-10 keV) in Small Window mode. The data have been analysed using SASv7.1 (Gabriel et al 2004). Several filtering criteria have been applied to the EPIC data, including filtering for time periods of high background activity following the standard procedure, and filtering only for single- and double-pattern events for EPIC-pn and single to quadruple for EPIC-MOS, as well as including only events with good quality (quality FLAG=0). For the spectral analysis, circular source and annular background extraction regions centered on the source are selected by maximizing the signal-to-noise ratio. The spectra are re-binned in order not to oversample the intrinsic energy resolution of the EPIC

cameras by a factor not more than 3, while making sure that each spectral channel contains at least 25 background-subtracted counts. This allows the use of the χ^2 quality-of-fit estimator to find the best fit model. Fits are performed in the 0.2-10 keV energy range simultaneously for the three EPIC cameras, where the systematic difference between the EPIC cameras is below $\sim 5\%$ in normalization. For the spectral analysis and fitting procedure XSPEC v12.4 (Arnaud 1996) is used. The data can be best described similar to the XRT data by a single power-law convolved with galactic and local absorption. Table 5 summarizes the observations along with the best fit model parameters.

The measurements reveal strong variability in X-rays on time scales of much less than one day. Fig 1 (panel C) and 4 show that the X-ray flux changed by a factor of two during the VHE high state on MJD 54625. This is comparable to observations of W Com with *BeppoSax* in 1998 by Tagliaferri et al (2000), where flux variations of a factor of three in less than 5 hours is reported. The X-ray flux during the VHE low state of June 2008 is very similar to the X-ray activity measured during the detection of W Com in March 2008 (see Figure 4).

2.4. Optical, Near-IR, UV and Radio Observations

Eight optical, one near-IR and three radio observatories contributed data sets to this campaign; see Table 1 for an overview. The majority of the observatories are part of the GLAST-AGILE Support Program (GASP, see Villata et al (2008)), a subgroup of the Whole Earth Blazar Telescope (WEBT³). In the period considered here, optical observations of W Com were carried out at the following observatories: Abastumani, Crimean, Roque de los Muchachos (KVA), Talmassons, Torino (for details concerning these observatories, see references provided by WEBT), San Pedro Martir, Northern Optical Telescope (NOT⁴) and Sapienza University (Italy). Magnitude calibration is obtained with respect to the photometric sequence by Fiorucci & Tosti (1996). Near-infrared (*JHK*) data were acquired at the AZT-24 telescope at Campo Imperatore Observatory (Italy). *Swift* UV/Optical Telescope (UVOT) (Romig et al 2005) observations were taken in the photometric bands of *UVW1* (centered at 2600 Å), *UVM2* (centered at 2246 Å), and *UVW2* (centered at 1928 Å) (Poole et al 2008). The *wvotsource* tool is used to extract counts from the UVOT, correct for coincidence losses, apply background subtraction, and calculate the source flux. The standard 5 arcsec radius source aperture is used, with a 20 arcsec background region.

At radio frequencies, data at 43 GHz were taken with the 32 m antenna at Noto (Bach et al 2007), at 14.5 GHz with the 26 m telescope of the UMRAO (Aller et al 2003), and at 36.8 GHz with the 13.7 m Metsähovi radio telescope (Teräsraanta et al 1998).

Data reduction of the optical and radio data followed standard methods and procedures, and we refer to the above papers for details. The near infrared, optical and UV data are corrected for absorption in our Galaxy using the dust maps of Schlegel et al (1998) and the extinction curve of Cardelli et al (1989). Since the blazar is observed in a bright state (see Section 3), a host galaxy contribution has not been subtracted.

3. Modeling and Discussions

The single-epoch SEDs for two different time intervals are shown in Fig. 5. The broad-band SEDs of W Com show double-humped structures, as found in all known gamma-ray blazars. The photon-production mechanism in these objects are successfully modeled by leptonic (e.g. Böttcher & Chiang (2002), Ghisellini & Madau (1996)) and hadronic model (e.g. Böttcher et al (2002), Mücke et al (2003), Aharonian (2000)). The data presented here have been modeled using a leptonic one-zone jet model. For this purpose, a quasi-equilibrium version of the model described in Böttcher & Chiang (2002) is adopted. In this model, the observed electromagnetic radiation is interpreted as originating from ultrarelativistic electrons (and positrons) in a spherical emission region of co-moving radius R_B , which is moving with a relativistic speed $\beta_\Gamma c$, corresponding to the bulk Lorentz factor Γ . Lacking more detailed constraints on the viewing angle θ between the jet direction and the line of sight, we fix θ to be the superluminal angle, for which the bulk Lorentz factor Γ equals the Doppler factor $D = (\Gamma[1 - \beta_\Gamma \cos \theta])^{-1}$, which determines the Doppler shift of photon energies and relativistic boosting of intensities. We note that our results mainly depend on D so that alternative combinations of Γ and θ yielding the same Doppler factor as the ones used in our model calculations are also possible, although minor differences in the flux of the external-Compton emission with respect to other radiation components (see below) would result (see, e.g., Dermer 1995).

In our calculations, the size of the emission region is constrained by the shortest observed variability time scale $\delta t_{\text{var, min}}$ through $R_B \leq c \delta t_{\text{var, min}} D / (1 + z)$. In the optical and X-rays (Böttcher et al 2002), variability down to time scales of a few hours has been observed, limiting the blob radius to $R_B \leq 10^{15} (\delta t_{\text{var, min}} / \text{hr}) (D/10)$ cm.

Ultrarelativistic electrons are assumed to be instantaneously accelerated into a power-law distribution in electron energy, $E_e = \gamma m_e c^2$, as $Q(\gamma) = Q_0 \gamma^{-q}$ with a low- and high-

energy cutoff γ_1 and γ_2 , respectively. An equilibrium between this particle injection, radiative cooling, and escape of particles from the emission region yields a temporary quasi-equilibrium state described by a broken power-law. The particle escape is parameterized through an escape time scale parameter $\eta > 1$ as $t_{\text{esc}} = \eta R/c$. The balance between escape and radiative cooling will lead to a break in the equilibrium particle distribution at a break Lorentz factor γ_b , where $t_{\text{esc}} = t_{\text{cool}}(\gamma)$. The cooling time scale is evaluated self-consistently taking into account synchrotron, synchrotron-self-Compton (SSC) and external Compton (EC) cooling. Depending on whether γ_b is greater than or less than γ_1 , the system will be in the slow cooling or fast cooling regime. In the fast cooling regime ($\gamma_b < \gamma_1$), the equilibrium distribution will be a broken power-law with $n(\gamma) \propto \gamma^{-2}$ for $\gamma_b < \gamma < \gamma_1$ and $n(\gamma) \propto \gamma^{-(q+1)}$ for $\gamma_1 < \gamma < \gamma_2$. In the slow cooling regime ($\gamma_b > \gamma_1$), the equilibrium distribution will be $n(\gamma) \propto \gamma^{-q}$ for $\gamma_1 < \gamma < \gamma_b$ and $n(\gamma) \propto \gamma^{-(q+1)}$ for $\gamma_b < \gamma < \gamma_2$. The number density of injected particles is normalized to the resulting power in ultrarelativistic electrons propagating along the jet,

$$L_e = \pi R_e^2 \Gamma^2 \beta_\Gamma c m_e c^2 \int_1^\infty \gamma n(\gamma) d\gamma. \quad (1)$$

The magnetic field B in the emission region is a free parameter. The corresponding Poynting flux along the jet is $L_B = \pi R_e^2 \Gamma^2 \beta_\Gamma c u_B$, with the magnetic energy density $u_B = B^2/(8\pi)$. For each model calculation, the resulting equipartition parameter, $e_B = L_B/L_e$, is evaluated. Modeling results of a large number of blazars, in particular flat-spectrum radio quasars, have shown that leptonic models can achieve reasonable fits with the emission region being close to equipartition, typically $0.1 \lesssim e_B \lesssim 1$. However, there is no a priori argument which would dictate quasi-equipartition. Therefore, while we disfavor possible fit results with e_B far from unity, we can not strictly rule out such scenarios.

Once the quasi-equilibrium particle distribution in the emission region is calculated, our code evaluates the radiative output from synchrotron emission, SSC, and EC emission self-consistently with the radiative cooling rates. For the EC component, we assume an external radiation field which is isotropic in the stationary AGN rest frame and can be approximated by a thermal blackbody with peak frequency ν_{ext} and radiation energy density u_{ext} . The latter two quantities are free model parameters. The direct emission from this external radiation field is added to the emission from the jet to yield the total model SED which we fit to the observations.

In all model calculations the luminosity distance to W Com has been calculated using standard Λ -CDM cosmology with $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$. Absorption of high-energy gamma rays by the extragalactic background light is taken into account using the model of

Franceschini et al (2008).

We fit the VERITAS flare detection and high X-ray state (MJD 54624.0 – 54626.0) with a pure SSC model, i.e., without any external radiation fields, and with a model with an EC component. A Doppler factor of 20 (i.e., $D = \Gamma = 20$) consistent with all observational constraints, and well in the range of Doppler factors commonly adopted in other blazar modeling works, allowed acceptable fits to the SEDs. We therefore fixed $D = \Gamma = 20$ for the remainder of the fitting procedure.

For a pure SSC fit, the free parameters were thus (1) L_e , the injection power of ultrarelativistic electrons into the emission region, (2,3) γ_1 and γ_2 , the cutoffs of the injected electron distribution, (4) q , the injection spectral index, (5) B , the magnetic field, (6), R_B , the radius of the emission region, and (7) η , the particle escape time scale parameter. The injection spectral index is tightly constrained by the observed X-ray energy spectral index $\alpha = q/2$, since electrons emitting synchrotron radiation in the X-ray regime are always above the critical Lorentz factor γ_b . The radius of the emission region is constrained through the minimum variability time scale of a few hours, as mentioned above. Together with the value of the magnetic field, the low-energy cutoff γ_1 , determines the location of the synchrotron and gamma-ray peaks in the SED, while the high-energy cutoff γ_2 influences the location of the high-energy cutoffs of the SED, in particular the synchrotron component. The cutoff of the SSC component is, in addition, strongly influenced by Klein-Nishina effects. Parameters of the SSC fit shown in Fig. 5 are listed in Table 6.

No SSC model fit was possible with the emission region being close to equipartition. Since there is virtually no observational constraint on the high-energy emission in the low (MJD 54626) and intermediate X-ray state (MJD 54631), we could choose a low injection power and relatively high magnetic field to achieve a synchrotron peak flux comparable to the flaring state, but at a much lower SSC flux. Such a choice of parameters allowed us to bring the system close to equipartition. However, almost any positive detection either in the Fermi or the VHE gamma-ray range could rule out this interpretation. In the SSC interpretation, the most significant difference between the various states consists of a change in the electron injection spectral index q from 2.55 in the flaring state to 3.50 and 3.40 in the low and intermediate state.

For a model with an EC component, two more parameters need to be specified: (8) the peak frequency ν_{ext} and the energy density u_{ext} of the external radiation field. As with the SSC model, the electron spectral index q is tightly constrained through the X-ray spectral index, while the variability time scale constrains the radius of the emission region. In order to avoid the problem of required large injection powers (to obtain a high SSC flux) and accordingly small magnetic fields (not to overpredict the synchrotron flux), the VHE gamma-ray

emission can be interpreted as external-Compton emission. In order for Comptonization of an external radiation field to be efficient out to gamma-ray energies of $E \gtrsim E_{\text{VHE}} = 300$ GeV, the external radiation field has to peak at energies $E_{\text{ext}} \lesssim (m_e c^2)^2 / E_{\text{VHE}} \sim 0.9$ eV, i.e., in the near-infrared. Therefore, line emission from a putative broad-line region (for which there is no evidence in W Comae), would have a too high photon energy characteristic to serve efficiently as a source photon field for EC scattering to produce an IC spectrum with peak energy near the VHE gamma-ray band. It is therefore more likely that infrared emission, e.g., from a near-nuclear dust torus, dominates the external radiation field responsible for EC emission at VHE gamma rays. We find that an external radiation field peaking at $\nu_{\text{ext}} = 1.5 \times 10^{14}$ Hz can, at the same time, serve as an efficient source for EC emission and explains the slight near-IR bump in the SED of W Comae. This bump could also be due to the host galaxy, and future observations of variability of the IR component or very high-resolution imaging are required to break this degeneracy. With the assumption of such an external radiation field, acceptable fits to each of the states of W Comae can be achieved within a factor of ~ 3 of equipartition. The parameters of our SSC+EC fit are listed in Table 6.

4. Conclusions

W Com belongs to the IBL class of blazars, a group with a now-growing number of VHE-detected blazars. Other blazars detected with VHE gamma rays that are not of the HBL class include the IBLs 3C 66A (Acciari et al 2009) and PKS 1424+240 (Ong et al 2009), low-frequency-peaked BL Lac objects (LBLs) such as BL Lacertae (Albert et al 2007), and the flat-spectrum radio quasar 3C279 (Albert et al 2008). In this article, we described a second VHE flare measured from W Com by VERITAS. The object was detected by VERITAS at a significance level of 10.3 standard deviations during 2008 June 7-8. The VERITAS observations triggered a multiwavelength campaign including AGILE gamma-ray, *Swift* and *XMM-Newton* X-ray, UV, optical and radio observations. We have carried out extensive modeling of the SED of W Com constructed from this contemporaneous multiwavelength data set, using a leptonic model considering synchrotron, SSC, and external-Compton emission. The SED can be modeled by a simple leptonic SSC model, but the wide separation of the peaks in the SED requires a rather low ratio of the magnetic field to electron energy density of $\epsilon_B = 2.3 \times 10^{-3}$. The SSC+EC model returns magnetic field parameters closer to equipartition, providing a satisfactory description of the broadband SED. These findings are similar to the results obtained from the first W Com VHE flare reported by Acciari et al (2008b).

The strong variability of W Com at X-ray and gamma-ray energies on time scales of days or less shows that only truly contemporaneous data can provide serious constraints on the various emission models. Future observations with VERITAS and the *Fermi Gamma-Ray Space Telescope* should provide even more detailed data to better resolve the short variability timescales, helping to further constrain model calculations.

This research is supported by grants from the US Department of Energy, the US National Science Foundation, and the Smithsonian Institution, by NSERC in Canada, by Science Foundation Ireland, and by STFC in the UK. We acknowledge the excellent work of the technical support staff at the FLWO and the collaborating institutions in the construction and operation of the instrument. Financial support by the Italian Space Agency through contract ASI-INAF I/088/06/0 is acknowledged. Support of UMRAO from NSF and University of Michigan is acknowledged. NVE and VML acknowledge support from RFBR grant 09-02-00092. The GASP-WEBT consortium is acknowledged. We acknowledge the efforts of the Swift team for providing the UVOT and XRT observations. This work was partially supported by NASA through XMM-Newton Guest Observer Program award No. NNX08AD67G and the Swift Guest Investigator Program award No. NNX08AU13G. The Metsähovi team acknowledges the support from the Academy of Finland.

Facilities: VERITAS, AGILE, Swift, XMM-Newton, GASP-WEBT

Table 1. Observatories contributing to the presented data set.

Waveband	Observatory	Frequency/Band/ Energy Range	MJD Range
Radio	UMRAO	14.5 GHz	54630-54633
	Metsähovi	36.8 GHz	54623-54634
	Noto	43 GHz	54611
NIR/Optical/UV	NOT	U/B/V/R/I	54636
	Tuorla	R	54622 - 54645
	Abastumani	R	54617 - 54637
	Sapienza University	R	54627 - 54634
	San Pedro Martir	R	54620 - 54624
	KVA	R	54626 - 54633
	Crimean	R	54623 - 54627
	Talmassons	R	54628
	Torino	R	54630
	Campo Imperatore	J/H/K	54627 - 54633
X-ray	Swift UVOT	U/B/V/UV	54625 - 54626
	Swift XRT	0.3-10 keV	54625 - 54626
	SuperAGILE	20-60 keV	54626 - 54630
	XMM-Newton EPIC	0.2-10 keV	54631 - 54635
HE Gamma-ray	AGILE GRID	30 MeV - 30 GeV	54626 - 54632
VHE Gamma-ray	VERITAS	0.1-30 TeV	54624 - 54626

Table 2. Details of VERITAS observations of W Com on 2008 June 7-9. The energy threshold for fluxes and upper flux limits (99% confidence level; assuming a photon index of $\Gamma = 3.68$) is 200 GeV. Errors are given at the 1σ level.

MJD	elevation range	observation time [min]	average pedestal variations ^a [dc]	significance (pre-trials) [σ]	flux or upper flux limit [$\text{cm}^{-2} \text{s}^{-1}$]
54624.16 - 54624.23	53-73°	100.2	7.8-8.0	8.9	$(5.0 \pm 0.8) \times 10^{-11}$
54625.17 - 54625.24	49-68°	100.2	8.1-9.7	7.9	$(6.2 \pm 1.2) \times 10^{-11}$
54626.18 - 54626.20	59-60°	32.0	12.2-12.3 ^b	-1.0	$< 3.21 \times 10^{-11}$

^aThe average pedestal variation in digital counts [dc] indicates the background light level. Values of 6.5 to 6.8 are typical for regular observations of extragalactic targets on moonless nights. All observations presented here are taken in moonlight conditions.

^bData taken with increased pixel (PMT) trigger threshold (at 70 mV CFD trigger threshold instead of the regular 50 mV).

Table 3. Details and results of the AGILE GRID observations of W Com on 2008 June 9-15. The energy threshold for fluxes and upper flux limits (99% confidence level; assuming a photon index of $\Gamma = 2.1$) is 100 MeV. Errors are given at the 1σ level.

MJD	significance (pre-trials)	flux or upper flux limits [$\text{cm}^{-2} \text{s}^{-1}$]
54626.75 - 54629.12	$< 3\sigma$	$< 60 \times 10^{-8}$
54629.12 - 54630.12	3.7σ	$(90 \pm 34) \times 10^{-8}$
54630.12 - 54632.50	$< 3\sigma$	$< 55.5 \times 10^{-8}$

Table 4. Details and results of the *Swift*/*XRT* observations of W Com 2008 June 7-9. The galactic $N_{H,Gal}$ has been fixed to a value of $1.88 \cdot 10^{20} \text{ cm}^{-2}$. The redshift of the source was assumed to be 0.102. Errors are given at the 1σ level.

MJD	Exposure [ksec]	Photon index Γ	Flux $F_{2-10\text{keV}}$ [$10^{-12} \text{ ergs cm}^{-2} \text{ s}^{-1}$]
54624.97 - 54624.98	0.52	2.49 ± 0.19	3.90 ± 0.97
54625.04 - 54625.05	0.84	2.71 ± 0.15	3.70 ± 0.76
54625.11 - 54625.12	1.38	2.55 ± 0.09	4.75 ± 0.55
54625.17 - 54625.20	2.51	2.36 ± 0.05	9.33 ± 0.74
54625.24 - 54625.27	2.47	2.59 ± 0.07	4.62 ± 0.37
54626.11 - 54626.21	5.07	2.69 ± 0.10	1.00 ± 0.18

Table 5. Details and results of the XMM-Newton observations of W Com 2008 June 14-18. The galactic $N_{H,Gal}$ has been fixed to a value of $1.88 \cdot 10^{20} \text{ cm}^{-2}$ as obtained from Dickney & Lockman (1990). The redshift of the source was assumed to be 0.102. Errors are given at the 1 sigma level.

MJD	Exposure [ksec]	N_H [10^{20} cm^{-2}]	Photon index Γ	Flux $F_{2-10\text{keV}}$ [$10^{-12} \text{ ergs cm}^{-2} \text{ s}^{-1}$]
54631.50 - 54631.55	28.0	$2.20^{+0.09}_{-0.09}$	$2.79^{+0.01}_{-0.01}$	$2.69^{+0.02}_{-0.02}$
54633.15 - 54633.17	16.0	$1.39^{+0.14}_{-0.13}$	$2.88^{+0.02}_{-0.02}$	$1.53^{+0.03}_{-0.02}$
54635.14 - 54635.16	11.0	$1.05^{+0.16}_{-0.15}$	$2.77^{+0.02}_{-0.02}$	$1.89^{+0.03}_{-0.03}$

Table 6: Parameters of SSC and SSC+EC fits to the SEDs of W Com on MJD 54624.0 – 54626.0.

Parameter	Symbol	SSC	SSC+EC
Doppler factor	D	20	20
Electron power [erg s ⁻¹]	L_e	3.4×10^{44}	5.7×10^{43}
Blob radius [cm]	R_b	3×10^{15}	10^{16}
Low-energy cutoff	γ_1	9×10^3	8×10^3
High-energy cutoff	γ_2	2.5×10^5	3×10^5
Electron injection index	q	2.55	2.55
Magnetic field [G]	B	0.24	0.35
B-field equipartition parameter	e_B	2.3×10^{-3}	0.32
Electron escape time scale parameter	η	300	300
Minimum variability time scale [hr]	$\delta t_{\text{var,min}}$	1.5	5.1
External radiation peak frequency [Hz]	ν_{ext}	–	1.5×10^{14}
External radiation energy density [erg cm ⁻³]	u_{ext}	–	2.4×10^{-4}

Fig. 1.— Multiwavelength light curve of W Com for MJD 54622 to 54636. Panel a: VHE gamma-ray light curve ($E > 200$ GeV) as measured by VERITAS. The flux in VHE gamma rays corresponds to approximately 25% of the flux of the Crab Nebula above 200 GeV. Panel b: Gamma-ray light curve ($E > 100$ MeV) as measured by AGILE. Panel c: X-ray (*Swift XRT*: 2-10 keV; circles; *XMM-Newton EPIC*: squares) Panel d: Swift UVOT (UVW1: squares; UVM2: downward-pointing triangles; UVW2: upward-pointing triangles) Panel e: Light curves of negative optical magnitudes (R-Band; filled circles: Tuorla; filled squares: Abastumani; filled triangles: San Pedro Martir; diamonds: Sapienza University; open circles: KVA; open squares: Crimean; open stars: NOT; open triangles: Torino; open crosses: Talmassons). Panel f: Radio light curve (circles: UMRAO 14.5 GHz; triangles: Metsähovi 37 GHz). Downward pointing arrows indicate upper flux limits (99% confidence level; Helene (1983)).

Fig. 2.— Sky map of significances of gamma-ray emission from the region around W Com. The background is estimated using the reflected region model (10 background regions, oversampling radius 0.12°). The position of W Com derived from radio data (Fey et al 2004) is indicated by a white cross. The dashed circles indicate positions of bright stars and their B-band magnitudes in the field of view; regions around these stars are excluded from the background estimation. Two sources listed in the Fermi bright gamma-ray source list (Abdo et al 2009a), and firmly associated with the blazars W Com and B2 1215 (Abdo et al 2009b), are shown with their 95% confidence area as circles with 'x' in their centre. The circle at the bottom right indicates the angular resolution of the VERITAS observations.

Fig. 3.— Differential VHE photon spectrum for W Com for MJD 54624.16 to 54625.24 (2008 June 7-8). The markers indicate measured data points and the continuous line a fit assuming a power-law distribution. Error bars show statistical errors only. For comparison, the photon spectrum of W Com derived from VERITAS measurements in March 2008 (Acciari et al 2008b) is indicated by a dashed line.

Fig. 4.— Spectral energy distribution for five different X-ray measurements with *Swift XRT* and *XMM-Newton EPIC* for 2008 June 7-18 and the *Swift XRT* measurements in March 2008 (MJD 54539.4).

Fig. 5.— High-state spectral energy distribution of W Com for MJD 54624 to 54626 including VERITAS, Swift XRT/UVOT, optical and radio data (filled circular markers). The averages of the optical, NIR and radio fluxes calculated over the time range from MJD 54610 to 54645 are shown here. Downward-pointing arrows indicate upper flux limits (99% confidence level) (Helene 1983). For comparison, the VERITAS, AGILE and Swift XRT/UVOT data for MJD 54626 to 54626.9 are shown as grey open squares and grey downward pointing arrows. Results from synchrotron-self-Compton (SSC) and external-Compton (SSC+EC) models are shown as continuous and dashed lines, respectively (see text for details). The different components (disk, sync=synchrotron, ec, ssc) of the SSC+EC models are indicated by dotted lines.
