## ABSTRACT

The joint observation of GW170817 and GRB170817A proved that binary neutron star (BNS) mergers are progenitors of short gamma-ray bursts (SGRBs): this established a direct link between the still unsettled SGRB central engine and the outcome of BNS mergers, whose nature depends on the equation of state (EOS) and on the masses of the NSs. We propose a novel method to probe the central engine of SGRBs based on this link. We produce an extended catalogue of BNS mergers by combining recent theoretically predicted BNS merger rate as a function of redshift and the NS mass distribution inferred from measurements of Galactic BNSs. We use this catalogue to predict the number of BNS systems ending as magnetars (stable or supramassive NS) or BHs (formed promptly or after the collapse of a hypermassive NS) for different EOSs, and we compare these outcomes with the observed rate of SGRBs. Despite the uncertainties mainly related to the poor knowledge of the SGRB jet structure, we find that for most EOSs the rate of magnetars produced after BNS mergers is sufficient to power all the SGRBs, while scenarios with only BHs as possible central engine seem to be disfavoured.

**Key words:** neutron star mergers – gamma-ray bursts – stars: magnetars.

## 1 INTRODUCTION

The discovery of GW170817, the first binary neutron star (BNS) merger event in the domain of gravitational waves (GWs; Abbott et al. 2017a), and its association with the short gamma-ray burst (SGRB) 170817A (Abbott et al. 2017b; Goldstein et al. 2017; Savchenko et al. 2017) provided the first direct proof that BNS mergers are indeed progenitors of SGRBs. However, the nature of the central engine powering SGRBs is still unsettled.

The outcome of a BNS merger mainly depends on the masses of the two compact objects and on the equation of state (EOS) of nuclear matter (see e.g. Shibata & Taniguchi 2006; Baiotti, Giacomazzo & Rezzolla 2008; Hotokezaka et al. 2011). Specifically, the BNS merger can form (i) a black hole (BH) from prompt collapse; (ii) a hypermassive neutron star (HMNS), which collapses into a BH in a very short time-scale, of the order of ms to  $\sim 100$  ms; (iii) a supramassive NS (SMNS), which collapses into a BH in a time-scale of the order of seconds, minutes, or longer; and (iv) a stable NS.

SMNSs and stable NSs endowed with large magnetic field and short spin period at birth (magnetars) are thought to be the central object powering GRBs (Dai & Lu 1998; Zhang & Mészáros 2001; Corsi & Mészáros 2009; Metzger et al. 2011). This proposal has been revealed itself very successful in reproducing the observed properties of the subclass of GRBs with X-ray plateau (Rowlinson et al. 2013) and/or SGRBs with extended emission (EE; Metzger, Quataert & Thompson 2008; Bucciantini et al. 2012), at least from

a phenomenological point of view (see e.g. Bernardini 2015; and Lü et al. 2020 for some recent results). Nevertheless, we are still lacking of a direct proof for the magnetar central engine. Alternative explanations for the observed X-ray plateau have been recently proposed in the framework of the structured jet model, without any assumption on the nature of the central engine (Beniamini et al. 2020; Oganessian et al. 2020). In addition, there are several theoretical limitations for the magnetar central engine, especially related to the difficulty for the magnetar to launch an ultra-relativistic jet (Ciolfi 2020).

For GRB 170817A, it was not possible to clearly establish the nature of the aftermath of the merger from the GW signal (see Abbott et al. 2017c, 2019a, c; see also the other confirmed BNS merger detected by LIGO and Virgo, GW 190425, described in Abbott et al. 2020a). The analysis of the electromagnetic (EM) emission from GRB 170817A seems to support the formation of a BH after a stage of HMNS lasting  $\sim 100$  ms (Margalit & Metzger 2017; Shibata et al. 2017; Radice et al. 2018; see, however, Piro et al. 2019). Anyway, this single case cannot exclude that magnetars may be the central engine of at least a fraction of SGRBs.

In this letter, we provide a new piece of evidence to approach this issue by investigating under which conditions the rate of magnetars (and BHs) produced in BNS mergers is sufficient to power SGRBs. We produce an extended catalogue of BNS mergers covering a volume comparable to the one of detection of SGRBs by combining the theoretically predicted BNS merger rate as a function of redshift and the NS mass distribution (Section 2). We use this catalogue to predict the rates of the different outcomes of the BNS merger for different EOSs and, comparing them to the rate of SGRBs in the

\* E-mail: [barbara.patricelli@pi.infn.it](mailto:barbara.patricelli@pi.infn.it)

same volume (Section 3), we discuss what is the most plausible scenario for the SGRB central engine (Section 4).

## 2 THE BNS MERGING SYSTEM CATALOGUE

We generate samples of synthetic BNS merging systems populating the Universe up to a redshift  $z = 1$ , according to a theoretically predicted cosmic BNS merger rate (see Section 2). We assign to each NS in the simulated BNS systems a mass, randomly extracted from a given mass distribution (see Section 2.2). The outcome of the simulated BNS mergers (that, as already said, can be an NS or a BH) is then estimated according to the masses of the two NSs and for different EOSs (see Section 2.3). In order to have enough statistics, we perform simulations corresponding to a total observing time of 20 000 yr.

### 2.1 The cosmic BNS merger rate

In this work, we use the cosmic merger rate density of BNSs ( $R_{\text{BNS}}$ ) estimated in Mapelli & Giacobbo (2018, hereafter M18); specifically, among the various models proposed, we use the one predicting a local merger rate of  $591 \text{ Gpc}^{-3} \text{ yr}^{-1}$ , which is consistent with current estimates obtained after the LIGO–Virgo detection of GW170817 and GW190425 (Abbott et al. 2020a).

To estimate the rate of events within  $z \leq 1$ , we proceed as follows. We assume standard flat Lambda cold dark matter cosmology with  $H_0 = 70.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_{\text{M}} = 0.2726$ ,  $\Omega_{\Lambda} = 0.7274$ , and  $\Omega_{\text{K}} = 0$ , as in Mapelli & Giacobbo (2018). The comoving volume element is

$$dV(z) = \frac{c}{H_0} \frac{D_c^2}{E(z)} d\Omega dz, \quad (1)$$

where  $c$  is the speed of light,  $d\Omega$  is the solid angle,  $E(z) = \sqrt{\Omega_{\text{M}}(1+z)^3 + \Omega_{\text{K}}(1+z)^2 + \Omega_{\Lambda}}$ , and  $D_c$  is the comoving distance, given by

$$D_c(z) = \frac{c}{H_0} \int_0^z \frac{dz'}{E(z')}. \quad (2)$$

The total BNS merger rate within a redshift  $z$  in the observer frame is then given by

$$n_{\text{obs}}(< z) = 4\pi \int_0^z \frac{R_{\text{BNS}}(z')}{(1+z')} \frac{dV(z')}{dz'} dz' \quad [\text{yr}^{-1}]. \quad (3)$$

### 2.2 The NS mass distribution

The masses of many NSs have been estimated in the past through both EM and GW observations. The smallest, precisely measured NS mass through EM observations is  $M = 1.174 \pm 0.004 M_{\odot}$ , as estimated for the companion of the pulsar J0453+1559 (Martinez et al. 2015). The most massive NS yet observed through EM observations is MSP J0740+6620, whose mass has been estimated to be  $M = 2.14^{+0.10}_{-0.09}$  (68 per cent credible interval, Cromartie et al. 2020). The masses of the NSs estimated from the GW detections of BNS mergers GW170817 (Abbott et al. 2019a) and GW190425 (Abbott et al. 2020a) are within this range when the spins are restricted to be within the range observed in Galactic BNSs. However, for GW190425, a higher mass for the one of the two NS is allowed when higher spins are considered (the mass of the primary component is in the range of  $1.61\text{--}2.52 M_{\odot}$ , see Abbott et al. 2020a).

In this work, we assume that both components of the binary systems have a mass distribution equal to the distribution inferred from measurements related to binary systems in the Galaxy: a

Gaussian function with central mass  $1.33 M_{\odot}$  and dispersion of  $0.09 M_{\odot}$  (Özel & Freire 2016); the two Gaussians are assumed to be uncorrelated. We also assume that the mass distribution does not change with redshift (see e.g. Eldridge, Stanway & Tang 2019; Mapelli et al. 2019).

### 2.3 The EOS and the BNS merger outcome

As already discussed, besides the NS initial masses (see Section 2.2), the other ingredient needed to determine which is the BNS merger remnant is the EOS. The EOS of cold, ultra-dense matter is still poorly constrained at high densities, despite decades of study (see e.g. Lattimer & Prakash 2001). A powerful instrument to better understand the properties of matter in the most extreme conditions, and therefore the EOS, is represented by GWs. Specifically, the most prominent effect of matter during the observed binary inspiral comes from the tidal deformation that each star’s gravitational field induces on its companion. For instance, the observation of GW170817 showed that ‘soft’ EOSs such as APR4 (Akmal, Pandharipande & Ravenhall 1998), which predict smaller values of the tidal deformability parameter, are favoured over ‘stiff’ EOSs such as H4 (Glendenning & Moszkowski 1991) and MS1 (Müller & Serot 1996), which predict larger values of the tidal deformability parameter and lie outside the 90 per cent credible region (Abbott et al. 2018). Other investigations have been done with the joint analysis of GW and EM data associated with GW170817 (see e.g. Margalit & Metzger 2017; Radice et al. 2018). Finally, further constraints on the EOS have been placed with a recent joint analysis of the NICER measurements of the mass and the radius of PSR J0030+0451 and of the GW data from GW170817 (see Raaijmakers et al. 2020).

To evaluate how the assumed EOS affects our estimates, in this work we use three different EOSs: APR4, MS1, and H4. These three EOSs cover a relatively wide range of maximum NS masses, but all with a maximum gravitational mass  $\gtrsim 2 M_{\odot}$ , consistent with the current observational EM limits. A more comprehensive set of EOSs will be considered in future studies.

To estimate the merger outcome for the various combinations of NS masses and EOS, we follow the approach proposed by Piro, Giacomazzo & Perna (2017). Specifically, we assume a reference mass lost from the system during the merger of  $M_{\text{lost}} = 0.01 M_{\odot}$ , we then convert the gravitational masses of the simulated NS to baryonic masses ( $m_{\text{b},1}$  and  $m_{\text{b},2}$ ) using the model developed by Piro, Giacomazzo & Perna (2017) for non-rotating NS<sup>1</sup> and for the three different EOSs; finally, we estimate the total barionic mass of the remnant as

$$M_{\text{b,tot}} = m_{\text{b},1} + m_{\text{b},2} - M_{\text{lost}}. \quad (4)$$

The value of  $M_{\text{b,tot}}$  is then compared with the maximum NS barionic masses to evaluate the nature of the remnant (see table 1 of Piro, Giacomazzo & Perna 2017). Remnants that are stable NSs or an SMNSs are considered as ‘magnetar-like’ GRB central engine.

## 3 THE RATE OF SHORT GAMMA-RAY BURSTS

The rate of SGRBs can be computed from their luminosity function and the redshift distribution. The luminosity function is usually

<sup>1</sup>As pointed out in Piro, Giacomazzo & Perna (2017), during the inspiral phase, the two NSs are not strongly affected by tidal coupling, so they are not spun appreciably and their structure is well approximated by non-spinning NS models.

modelled as a single or broken power law, derived by fitting the peak flux distribution of SGRBs detected by BATSE or Fermi/GBM (Guetta & Piran 2005, 2006; Hopman et al. 2006; Nakar, Gal-Yam & Fox 2006; Salvaterra et al. 2008; Virgili et al. 2011; D’Avanzo et al. 2014; Wanderman & Piran 2015; Ghirlanda et al. 2016). The redshift distribution is assumed to follow the cosmic star formation rate with a delay due to the time necessary for the progenitor binary system to merge, and compared with that of the few SGRBs with measured  $z$ .

In this work, we adopt the SGRB rate derived by Ghirlanda et al. (2016, hereafter G16), that is the most robust up to date because it is derived using all the available observer-frame constraints (i.e. peak flux, fluence, peak energy, and duration distributions) of the large population of Fermi/GBM SGRBs and the rest-frame properties of a complete sample of SGRBs detected by Swift (D’Avanzo et al. 2014). In particular, we use the rates derived under two possible assumptions: that the intrinsic  $E_p - L_{\text{iso}}$  and  $E_p - E_{\text{iso}}$  correlations hold (case ‘a’ in G16, red solid line in Fig. 1), or that the distributions of intrinsic peak energy, luminosity, and duration are independent (case ‘c’ in G16, orange solid line in Fig. 1).

In order to directly compare these rates to the ones for BNS mergers derived in the previous section, one should account for the fact that SGRB emission is collimated. Thus, we assign to each BNS system a random inclination of the orbital plane with respect to the line of sight, and we assume that the GRB jet axis is perpendicular to the plane of the binary’s orbit (i.e. that the angle of the observer with respect to the jet is equal to the inclination angle of the BNS system). We draw from our sample the BNS mergers whose inclination angle is  $\theta_i \leq \theta_j$ , with  $\theta_j$  the GRB jet opening angle. The jet opening angle is poorly constrained for SGRBs since the weakness of the afterglow makes a clear detection of a jet break challenging. The few estimates available range from  $3^\circ$  to  $8^\circ$  (see e.g. Fong et al. 2014, and references therein). Recently, Ghirlanda et al. (2019) performed high spatial resolution measurements of the source size and displacement of the SGRB 170817A with Very Long Baseline Interferometry observations, favouring a structured jet model: a successful jet with a structured angular velocity and energy profile, featuring a narrow core with opening angle  $\theta_c = 3.4 \pm 1^\circ$ . This jet structure might be a common feature of SGRBs (quasi-universal, Salafia et al. 2015). In this scenario, the luminosity function of SGRBs would be dominated at low luminosity by events seen with large viewing angles that are detectable in the local Universe (see e.g. Salafia et al. 2020). However, the rates derived by G16 correspond to SGRBs that are seen within (or close to) the inner core (Salafia et al. 2020). We thus assume  $\theta_j$  to be in the range  $3-8^\circ$ , with a reference value of  $5^\circ$ .

Within the total number of SGRBs, it is possible that only a fraction of them are powered by magnetars. The magnetar central engine has been advocated to interpret phenomenologically observational features related only to specific subclasses of SGRBs: those with an X-ray plateau, and those with an EE. The first subclass comprises those SGRBs that exhibit a flattening in the X-ray afterglow between  $100 - 10^4$  s after the main event, possibly caused by the spin-down radiation of the magnetar that is expected to emit a relativistic wind at time-scales comparable to the observed ones (Dai & Lu 1998; Zhang & Mészáros 2001; Corsi & Mészáros 2009; Metzger et al. 2011). The presence of a plateau phase is a feature common to  $\sim 50$  per cent of SGRBs (Rowlinson et al. 2013; D’Avanzo et al. 2014). The other subclass is characterized by having a re-brightening in the prompt emission after the initial spike lasting up to  $\sim 100$  s (Norris & Bonnell 2006), observed in  $\sim 15$  per cent of cases (Berger 2014). This long-lasting emission can be explained in the context of the magnetar central engine as produced by either a relativistic wind powered by the magnetar rotational energy (Metzger et al. 2008;

Bucciantini et al. 2012; Yu, Zhang & Gao 2013; Metzger & Piro 2014; Siegel & Ciolfi 2016a, b), or by a magnetic ‘propeller’ that ejects the material from the accretion disc surrounding the newly formed magnetar (Gompertz, O’Brien & Wynn 2014).

## 4 RESULTS AND DISCUSSION

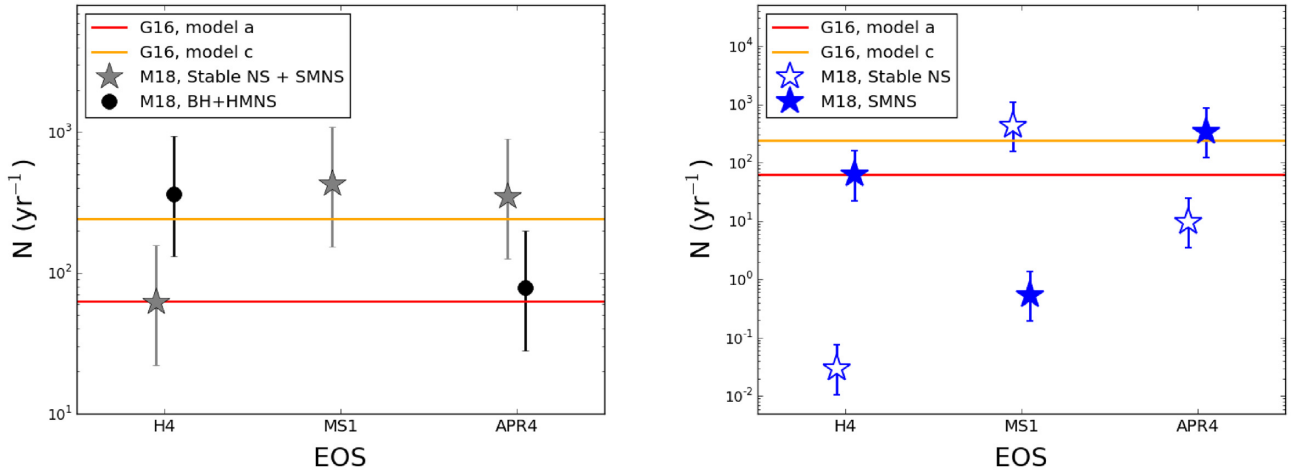

In this work, we aim at assessing if the magnetars (either stable NSs or SMNSs) produced by BNS mergers are sufficient to power at least a fraction of SGRBs. We thus compare the observer-frame BNS merger rate giving rise to a magnetar, for the different EOSs and within redshift  $z = 1$ , with the total rate of SGRBs in the same volume, as derived in G16 under two different assumptions (model ‘a’ and ‘c’). The results are shown in Fig. 1, left-hand panel.

The percentage of BNS mergers ending as a magnetar changes according to the assumed EOS: it is  $\sim 14$  per cent,  $\sim 82$  per cent, and  $\sim 100$  per cent for the H4, APR4, and MS1, respectively.<sup>2</sup> The total rates obtained with APR4 and MS1 are consistent with the total rate of SGRBs for the range of beaming angles considered (see Section 3), implying that in principle all the SGRBs can be powered by magnetars. The H4 EOS predicts a rate of magnetars that is consistent with model ‘a’ of G16, while is only marginally consistent with model ‘c’ if we assume larger values of  $\theta_j \sim 10^\circ$ . The total number of newly born magnetars produced in BNS mergers is dominated by SMNSs for the APR4 and H4 EOSs (see Fig. 1, right-hand panel). Thus, if we want to explain the X-ray plateau or the EE with the magnetar model, we need to require that in at least a fraction of SGRBs ( $\sim 50$  per cent), the SMNS survives for long enough ( $\sim$  minutes to hours) after the merger. This is not the case for MS1, where the number of stable NSs is sufficient to power all SGRBs (see Fig. 1, right-hand panel).

As an opposite case, we also compare the rate of BHs and HMNSs (BH+HMNS) produced after the merger of on-axis BNS systems for the different EOSs to the total rate of SGRBs (see Fig. 1, left-hand panel). We group these two cases because in both scenarios the SGRB is thought to be powered by the BH formed either promptly or after the rapid collapse of the HMNS and they are distinguishable only with complementary observations (GWs and kilonova emission), as it happened for GRB 170817A (Margalit & Metzger 2017; Shibata et al. 2017; Radice et al. 2018). Only for the EOS H4, the rate of BH+HMNSs is high enough to account for all the SGRBs. For the EOS APR4, the rate of BH+HMNSs is consistent with the rate of SGRBs predicted by model ‘a’ of G16, but is consistent with the rate predicted by model ‘c’ of G16 only assuming larger  $\theta_j \sim 9^\circ$ . For the EOS MS1, the rate of merging BNS systems ending as a BH or an HMNS is negligible. This indicates that, at least for the APR4 and MS1 EOSs, BH as the only possible SGRB central engine is even disfavoured.

These results only consider the remnants of merging BNS systems formed through isolated binary evolution, that are thought to give the dominant contribution to the total BNS merger rates (see e.g. Santoliquido et al. 2020; Ye et al. 2020). The contribution from systems formed through dynamical assembly is not expected to change the conclusions of this paper; a detailed investigation on this will be performed in future works. We don’t include in our study BNS merging systems as massive as the progenitor of GW190425. The formation of such heavy BNS systems, not yet observed through

<sup>2</sup>These figures are slightly different with respect to the ones presented in Piro, Giacomazzo & Perna (2017) because of the different mass distribution used in this work.

**Figure 1.** Event rates within redshift  $z = 1$ . The solid red and orange lines represent the rate of SGRB, as estimated from the models ‘a’ and ‘c’ of G16, respectively. Left-hand panel: the star (circle) represents the merger rate of BNS systems with  $\theta_i \leq \theta_j = 5^\circ$  (see Section 3) ending as a stable NS or an SMNS (HMNS or BH) for different EOSs, estimated using the M18 BNS cosmic merger rate; the error bars represent the merger rate interval corresponding to the assumed range of values of  $\theta_j$ :  $3\text{--}8^\circ$  (see Section 3). Right-hand panel: the empty (filled) blue star represents the merger rate of BNS systems ending as a stable NS (SMNS) for different EOSs, estimated using the M18 BNS cosmic merger rate.

EM waves, is challenging for current population synthesis models (see e.g. Safarzadeh, Ramirez-Ruiz & Berger 2020, and references therein); future GW observations will be crucial to confirm their existence,<sup>3</sup> to understand which is their formation mechanism, to better constrain the associated merger rate and also to complement the mass distribution of Galactic BNSs: this could potentially modify the results here presented, possibly leading to an increase in the rate of BH remnants.

Another possible progenitor system for SGRBs that leads to the formation of a BH is the coalescence of an NS–BH system. Since the NS–BH mergers have a very different range of mass ratios with respect to the NS–NS case, SGRBs produced via this channel should have distinct properties compared to the subclass produced via NS–NS merger. However, no conclusive dichotomy is found so far to support the production of an important fraction of SGRBs via this progenitor channel (Gompertz, Levan & Tanvir 2020), though SGRBs with EE have been tentatively associated with NS–BH progenitors (Troja et al. 2008; Gompertz et al. 2020). In addition, the rate of NS–BH systems could also be much smaller than the one of BNSs (e.g. Belczynski et al. 2020), especially those with mass ratios such that the NS is disrupted and not swallowed whole (e.g. Foucart et al. 2014, 2017). The LIGO and Virgo collaborations did not report any confirmed detection of NS–BH mergers so far,<sup>4</sup> and they put an upper limit on the NS–BH merger rate of  $610 \text{ Gpc}^{-3} \text{ yr}^{-1}$  (see Abbott et al. 2019b). For these reasons, neglecting the contribution to the rate of SGRBs from NS–BH progenitors does not affect our conclusions about the magnetar central engine, while this progenitor type provides a complementary way to produce BH central engine.

While with this work, we have clearly shown that the rate of magnetars produced in BNS mergers is high enough to power SGRBs, from Fig. 1 it is evident that our current knowledge of the SGRB rate does not allow us to distinguish among the different

EOSs. The major source of uncertainty is the poor constraints that we have on the jet opening angle due to the faintness of their late-time afterglows that makes the detection of jet-breaks challenging. Dedicated campaigns to monitor late-time evolution of the afterglows are needed to put constraints on the jet structure: this will result also, as a by-product, in a more robust estimate of the true event rate that might be used to constrain the EOSs. Future missions such as Athena will be key instruments to this scope (Jonker et al. 2013). In addition to this, in the next years, when current generation GW detectors will operate with increased sensitivity, we expect that more BNS mergers will be detected, possibly with EM counterparts: this will allow us to put tighter constraints on the merger rates of these systems and, jointly to a deeper understanding of the EOS, to better probe the magnetar–SGRB connection. The possibility to detect post-merger signals with the third-generation GW detectors as the Einstein Telescope (Andersson 2017) will be the ultimate proof to unambiguously identify the central engine of SGRBs.

## ACKNOWLEDGEMENTS

The authors thank Michela Mapelli for providing the cosmic binary neutron star merger rate density used in this work, and Riccardo Ciolfi, Paolo D’Avanzo, Giancarlo Ghirlanda, and Anthony Piro for useful discussions. The authors also thank the anonymous referee for his/her valuable comments and suggestions, which helped us to improve this work.
