**Evidence has increasingly mounted in recent decades that outflows of matter and energy from the central parsecs of our Galaxy have shaped the observed structure of the Milky Way on a variety of larger scales<sup>1</sup>. On scales of  $\sim 15$  pc, the Galactic centre (GC) has bipolar lobes that can be seen in both X-rays and radio<sup>2,3</sup>, indicating broadly collimated outflows from the centre, directed perpendicular to the Galactic plane. On far larger scales approaching the size of the Galaxy itself, gamma-ray observations have identified the so-called "Fermi**

**Bubble” (FB) features<sup>4</sup>, implying that our Galactic centre has, or has recently had, a period of active energy release leading to a production of relativistic particles that now populate huge cavities on both sides of the Galactic plane. The X-ray maps from the *ROSAT* all-sky survey show that the edges of these cavities close to the Galactic plane are bright in X-rays. At intermediate scales ( $\sim 150$  pc), radio astronomers have found the Galactic Centre Lobe (GCL), an apparent bubble of emission seen only at positive Galactic latitudes<sup>5,6</sup>, but again indicative of energy injection from near the Galactic centre. Here we report the discovery of prominent X-ray structures on these intermediate (hundred-parsec) scales above and below the plane, which appear to connect the Galactic centre region to the *Fermi* bubbles. We propose that these newly-discovered structures, which we term the Galactic Centre Chimneys, constitute a channel through which energy and mass, injected by a quasi-continuous train of episodic events at the Galactic centre, are transported from the central parsecs to the base of the *Fermi* bubbles<sup>5</sup>.**

Figure 1 shows an X-ray map of the central  $\sim 300 \times 500$  parsec of the Milky Way, providing us with an unprecedented view of the Galactic corona, which we obtained via observations with the *XMM-Newton* satellite between 2016 and 2018, in addition to archival data<sup>7</sup>. Strong, low-energy photo-absorption that hinders the mapping of the large-scale diffuse emission in the GC region with *ROSAT* is alleviated in this image by using the wider energy band of *XMM-Newton* (see Methods). The Galactic supermassive black hole, Sgr A\*, and its surrounding central cluster of massive stars<sup>8</sup>, are located at the centre, as are the  $\pm 15$  pc bipolar lobes, visible as a barely resolved small white region perpendicular to the plane. The striking new features in this image

are the elongated and slightly edge-brightened structures ( $\gtrsim 1^\circ$  or 160 pc across) to the North and South of Sgr A\*. We refer to these quasi linear features, which appear to connect the GC to the Galactic bulge, as the northern and southern Galactic Centre Chimneys. The northern Chimney is roughly co-spatial with the GCL. Both Chimneys share comparable X-ray brightness and colour. This suggests that they have a common origin that is most likely connected with the Galactic centre, and a common emission mechanism. Despite their similarities, the northern and southern Chimneys are not strictly symmetric about the Galactic plane, which can plausibly be attributed to “Galactic weather”, i.e., the differences in the rich interstellar medium (ISM) structures above and below the plane that interact/interfere with the GC outflows of mass and energy that have presumably hewed the Chimneys.

Parallel to the plane, the breadth of the newly discovered features is limited to  $\pm 50$  pc ( $\pm 0.4^\circ$ ), while in the latitudinal direction, the Chimneys span more than a degree above and below the plane, where they merge with much more extended warm plasma emission seen by *ROSAT* and tentatively identified as the X-ray counterparts of the *Fermi* bubbles (see Fig. 5; <sup>4,9</sup>). Towards the plane, the Chimneys can be traced down to  $b \sim \pm 0.2^\circ$ . Morphologically, they appear to originate from a region within  $\sim 50$  pc of Sgr A\*, with the  $\pm 15$  pc bipolar lobes nested at the centre.

These  $\pm 15$  pc bipolar lobes are traced down to parsec scale by plasma with temperature  $kT \sim 0.7 - 1$  keV. Their X-ray surface brightness declines rapidly with latitude  $I_x \propto b^{-2}$  to  $b^{-3}$  between a few to  $\sim 15$  pc, indicating a strong pressure gradient (see Fig. 2, <sup>3<sup>10,7</sup></sup>). Such a pressure gradient cannot be compensated by the gravitational potential of the central region;

Figure 1: X-ray emission from the central 300 by 500 parsecs of the Milky Way. The RGB image shows, in red: integrated emission in the energy range 1.5-2.6 keV; green: integrated emission from 2.35 to 2.56 keV, corresponding to the S XV transition; blue: continuum emission in the 2.7-2.97 keV band, therefore not contaminated by the intense S XV and Ar XVII lines<sup>7</sup>. Sgr A\*, the electromagnetic counterpart of the supermassive black hole, and the central cluster of massive stars are located at the centre. A coherent edge-brightened shell-like feature with a diameter of  $\sim 160$  pc, dubbed the "Chimney", is present north of Sgr A\*. The shell is roughly co-spatial with the radio feature known as the Galactic centre lobe<sup>6</sup>. Diametrically opposite to the Chimney with respect to Sgr A\* is the newly-discovered, bright elongated feature, the southern Chimney. The north and south features have comparable brightness, extent and colour, suggesting a similar emission process (see white dashed regions). Their relative placement suggests a common origin located close to Sgr A\*. The white arcs correspond to the low-latitude edges of the *Fermi* bubbles, as traced by *ROSAT* X-ray emission at higher latitude (see Fig. 5). Point sources have been removed. Larger circles correspond to regions that have been excised to remove the dust scattering haloes around bright sources.

Figure 2: Latitudinal variation of the physical parameters of the Galactic centre corona. Positive values indicate Galactic North. The latitude is given in parsecs, assuming that the emission is located at the Milky Way centre. From top to bottom latitudinal profiles of column density of neutral absorbing material, temperature and surface brightness (see Methods) of the X-ray emitting thermal plasma at  $l = 0^\circ$ , as derived from the fit of the *Chandra* (black squares) and *XMM-Newton* (red squares) spectra (see Fig. 9). Grey stars show the latitudinal profile at  $l = -0.7^\circ$  as derived from the fit to *XMM-Newton* spectra (see Methods).

Figure 3: Surface brightness, density and pressure latitudinal profiles of the Galactic centre corona. Black and red symbols refer to fits to the data (at  $l = 0^\circ$ ) for the northern and southern Chimneys, respectively. Similar characteristics are found for the northern and southern Chimneys. Stars and squares show results from *XMM-Newton* and *Chandra*, respectively. Grey stars show the latitudinal profile at  $l = -0.7^\circ$ . To estimate densities and pressure, we assumed that the  $\pm 15$  pc Sgr A lobes have depths of 15 pc, while all other regions have depths of 150 pc (e.g., the Chimneys as well as the high latitude emission, etc.). Although the  $l = -0.7^\circ$  points are at the same Galactic latitude as the  $l = 0^\circ$  points, they are characterised by a smaller density and pressure. The grey dotted and dashed lines show the density stratification for a static/non-rotating and isothermal atmosphere embedded in the gravitational potential of the Milky Way with temperature of  $kT = 0.6$  and 1 keV, respectively. The curves are normalised in order to reproduce the densities observed at  $l = -0.7^\circ$ . The densities within the Chimneys are larger by a factor of  $\sim 2 - 3$  compared with the expectations, while the  $\pm 15$  pc bipolar lobes are more than an order of magnitude larger than expected by the Milky Way gravitational potential. Nevertheless, the roughly factor of 2 drop in densities within the Chimneys is likely related to the drop of Milky Way potential.

Figure 3: Continued: Temperature vs. density profiles of the Galactic corona. Two different adiabatic laws are required to interpolate the  $\pm 15$  pc bipolar lobes and the Chimneys. Therefore, if both features are filled with warm X-ray emitting plasma, this indicates that the Chimneys and the  $\pm 15$  pc lobes are the manifestation of two distinct outflows.

therefore the gas in the bipolar lobes must be outflowing (Fig. 3). Under the assumption of freely expanding conical or paraboloidal outflow<sup>11</sup>, the temperature should drop rapidly with latitude due to adiabatic expansion, converting it into a fast and cold gas stream. Such scenarios are often invoked for the extra-planar outflows in star-forming galaxies<sup>12,13,14</sup>, where the observed X-rays are merely tracers of a much more powerful energy- and mass-loaded outflow.

Alternatively, the observed X-rays could be coming from the shock-heated gas that surrounds the lobes, reminiscent of AGN-inflated bubbles in galaxy clusters. In this scenario, the temperature of the gas would characterise the expansion velocity of the lobes.

To obtain a conservative limit on the power of the  $\pm 15$  pc structure, we assume that the X-ray gas is volume filling and the outflow velocity is comparable to the sound speed,  $c_s \approx 500 \text{ km s}^{-1}$ , set by the gas temperature. The thermal energy of the  $\pm 15$  pc lobes is then  $\sim 6 \times 10^{50}$  ergs and

the power of the outflow averaged over the sound-crossing time of the lobes,  $t_s \sim 3 \times 10^4$  yr, is  $L_{15 \text{ pc}} \sim 8 \times 10^{38}$  erg s<sup>-1</sup>. These are relatively modest requirements in terms of the time-averaged energetics that could be satisfied by accretion-powered events from the Galactic centre black hole, which may arise e.g., from tidal disruption of stars, releasing  $10^{51-52}$  erg every few  $10^4$  yr<sup>15,16</sup> and/or by supernovae explosions in the central star cluster<sup>17</sup>. If the X-ray emitting gas has a very low filling factor, then the actual energetics of the  $\pm 15$  pc outflow could be much larger than the values quoted above.

At latitudes larger than  $\pm 15$  pc, the X-ray emission from the  $\pm 15$  pc bipolar lobes blends into the more extended emission of the newly discovered Chimneys. Within the northern Chimney, the plasma temperature remains roughly constant at  $kT \sim 0.7 - 0.8$  keV over its entire extent ( $\sim 160$  pc; Fig. 2). This and the shell-like morphology of the northern Chimney are easily understood if this mild outflow encounters a cap partly obstructing its further latitudinal expansion<sup>6</sup>. The density within the Chimneys gently decreases with latitude from  $\sim 0.2$  at 30 pc to  $\sim 0.1$  cm<sup>-3</sup> at 160 pc. The thermal energy in the Chimneys, derived from the X-ray data as is done above for the  $\pm 15$  pc lobes, is  $\sim 4 \times 10^{52}$  erg. Using again the sound crossing time of the 160 pc structure ( $t_s \sim 3 \times 10^5$  yr) as an estimate for the energy replenishment time, one gets the power  $L_{160 \text{ pc}} \sim 4 \times 10^{39}$  erg s<sup>-1</sup>. Although this is a factor of 5 higher than the estimated power for the  $\pm 15$  pc lobes, it is still consistent with the supernovae or tidal disruption scenarios. Note that for the plasma in the Chimneys, the Galactic gravitational potential may not be negligible; therefore the  $kT \sim 0.7$  keV plasma might be close to hydrostatic equilibrium (Fig. 2), rather than outflowing at the sound speed. In this scenario, the Chimneys testify the channel excavated by the powerful

outflows associated with a series of past episodic events and connecting the GC with the halo. The past outflows might have been even more collimated than its relics (the Chimneys) appear today. The long cooling time ( $t_{cool} \sim 2 \times 10^7$  yr) and the shallow density gradient in the vertical direction do not contradict this scenario. However, the edge-brightened morphology of the Chimneys rather favours the dark (e.g., cold or low density) flow scenario, when X-rays at the edges are due to the flow interaction with the denser ISM.

The Chimneys appear to be well confined in the longitudinal direction, except for a “protrusion” on the eastern side of the northern Chimney (see Methods), and they have sharp edges along much of their vertical extent (Fig. 6). Given the estimated pressure of the X-ray emitting gas in the Chimneys ( $P \sim 0.1 - 0.2$  keV cm<sup>-3</sup>) it seems plausible that either dense ISM phases or magnetic pressure ( $B \sim 60 - 90$  μG would be required) can provide the necessary confinement. For example, radio surveys of the central few degrees indicate a rather strong magnetic field<sup>18,19,20</sup>, rising vertically from the central molecular zone. The almost cylindrical shape of the Chimneys and their widths of  $\sim 100$  pc at  $b > \pm 0.2^\circ$ , raises the possibility that they are formed by a distributed energy injection process in the plane, evidence that would favour a star-formation powered scenario. This is corroborated by the observations that the majority of the evolved massive stars of the central molecular zone are concentrated at the feet of the Chimneys<sup>21,22</sup>. It is worth noting that for a flow through a channel with a constant cross section, the pressure experiences a modest drop [factor of  $\sim 2$ ] along the cylindrical part of the channel (due to the acceleration of the gas and the Galactic gravitational potential), but can drop dramatically once the channel flares. The observed temperature of the gas in the Chimneys, if viewed as a proxy for a typical energy-per-particle value for

injected energy and mass, also appears to be within a factor of few from what is usually assumed in star-formation driven scenarios<sup>23</sup>.

In the direction perpendicular to the Galactic plane, the Chimneys extend beyond one degree, where they appear to merge with the FB, as suggested by the extrapolation of the boundaries of the extended structures seen in *ROSAT* images to small latitudes (Fig. 5, 7<sup>24</sup>). We tentatively associate the transition from the Chimneys to the FB with a modest drop of temperature, which in the northern Chimney occurs  $\sim 160$  pc above the plane. In the surface brightness distribution, the transition is also relatively inconspicuous.

With these new data, two questions arise. One is whether the inner  $\pm 15$  pc bipolar lobes and the larger 160 pc Chimneys are parts of the same outflow that starts very close to Sgr A\*. While this cannot be entirely excluded due to the likely intermittency of the energy release, the X-ray data do not directly support the idea that the Chimneys are a continuation of the inner lobes. For instance, the density-temperature relations shown in Fig. 3 indicate that the entropies associated with these two flows are markedly different, as shown by the data following two separate adiabatic relations ( $kT \propto n^{2/3}$ ). Rather, the inner lobes appear to be embedded into the volume occupied by the larger Chimneys. At the same time, the hypothesis that both structures are powered by the same physical mechanism cannot be excluded. One plausible candidate for such a universal mechanism is the energy released by supernovae. In this scenario, it is the strongly uneven distribution of massive stars over the GC region (one concentration close to Sgr A\* and another one distributed over  $\pm 50$  pc) that leads to the nested appearance of two outflows, rather than to a single one.

The hypothesis in this paper is that the Chimneys could be the channel that transports the energy from the active GC region to the FB. Their morphology does suggest so. The various estimates of the power needed to create and sustain the FB differ by several orders of magnitude, from few  $10^{40}$  to  $10^{44}$  erg s<sup>-1</sup>, depending on the assumed source of energy and its intermittency<sup>4,25,26</sup>. The lower end of these estimates is within an order of magnitude of the Chimney energetic, which is plausibly a lower limit. The “low-power” models are predominantly associated with quasi-continuous star formation wind scenarios<sup>25,27,28</sup> and the observed morphology of the Chimney is reminiscent of these wind models, albeit with some modifications, e.g., related with the shape of the “nozzle” that confines the flow over  $\sim 100$  pc. In the supernovae-powered scenario described above, the role of Sgr A\* (and the  $\pm 15$  pc bipolar lobes) is subdominant, assuming that the distribution of massive stars is a good proxy for the energy release. However, extremely energetic events associated with accretion episodes onto Sgr A\*, like tidal disruption events and instances of Seyfert-like activity, remain a viable scenario too<sup>29,30</sup>. In this case, the channel created by the Chimneys could alleviate the propagation of matter and energy from Sgr A\* to the rarefied and low pressure regions above the disc (see, e.g.,<sup>27</sup>).

Irrespective of their primary source, the GC Chimneys reveal the exchange of energy, plasma and metals between galactic disks and their bulges and they provide preferential channels to connect galactic centres to their halos. Understanding the outflows produced by the low level of accretion onto Sgr A\* and star-formation at low rates is of central importance to learning about processes surrounding low luminosity active galactic nuclei and quiescent galaxies.

## Methods

**Data reduction and analysis** The basis of our results are smoothed X-ray images in different energy bands and spectra of the diffuse X-ray emission of the innermost Galactic corona. The X-ray maps are based on two recent *XMM-Newton* large observing programs comprising 46 observations of 25 ks exposure (see Fig. 4), in addition to all the available archival data (mainly concentrating on the scan of the central molecular zone<sup>7</sup>). All new observations are performed with the European Photon Imaging Camera (EPIC) PN<sup>31</sup> and MOS CCDs<sup>32</sup>, in full-frame CCD readout mode with the medium optical filters applied. The *XMM-Newton* data reduction was performed using the Science Analysis System (SAS) version 16.1.0. For more details on the analysis pipeline see <sup>33,7</sup>. Data products were downloaded from the respective archives, we screened times of high background and removed point sources. Detector background files were created and subtracted using the task `evqpb`, summing up filter-wheel-closed (FWC) files with 10 times the exposure of each observation.

We also used archival observations with the *Chandra* Advanced CCD Imaging Spectrometer<sup>34</sup> imaging (-I) CCD array (about 0.1 to 10 keV energy range). The *Chandra* ACIS-I observations were reprocessed using the *Chandra* Interactive Analysis of Observations software package<sup>35</sup> version 4.5 and the *Chandra* Calibration Database version 4.5.9. For a detailed description of the data reduction pipeline see <sup>36</sup>. We estimated the background in each *Chandra* observation via the CIAO tool `acis_bkgnd_lookup`, which delivers a suitable blank-sky background file, provided by the *Chandra* X-ray centre<sup>37</sup>. The *Chandra* data have an exposure of about 50 ks in the central scan, 15 ks in the vertical extensions, and 2 ks in the large areas at higher latitude (see Fig. 7).

The combination of *Chandra* and *XMM-Newton* data provides the highest spatial ( $\sim 1$  arcsec) and spectral resolution ( $\sim 100$  eV full width half maximum, FWHM) available in soft X-rays.

For the *XMM-Newton* data we performed source detection on each individual observation and all detected point sources have been masked out. Readout streaks were included in background images. For *Chandra* data, we performed source detection on all datasets, simultaneously in multiple energy bands. A second point source detection was run on the merged images and, after carefully screening the detection list, the point sources were masked out from the image (in some cases additional regions were masked to screen dust-scattering halos and readout streaks of very bright sources). We then computed the background subtracted, exposure-corrected and adaptively smoothed images, resulting into smoothed flux images of diffuse emission (foreground, unresolved point sources, and intrinsic GC hot plasma emission).

The flux images were then binned into regions of equal signal-to-noise (S/N) ratio 50 ( $> 2.5 \times 10^3$  counts per bin) for *Chandra* and S/N 100 ( $> 1 \times 10^4$  counts per bin) for *XMM-Newton*. The difference was chosen due to more stable background in *Chandra* compared to *XMM-Newton*. The contour binning technique `contbin`<sup>40</sup> was used for this task. For each observation overlapping with one of the bins, spectra and response files were created and all contributions were added with proper weighting to obtain one spectrum for each spatial bin. These small scale bins were then added up to obtain higher S/N spectra for regions of interest (see Figs. 9 and 10). Each of the regions shown in Figs. 9 and 10 consists of 5-7 merged initial bins. The spectra in the 0.5-7 keV energy range were then fitted with emission models using `XSPEC`<sup>41</sup> version 12.9.1n. The best fit parameters were used to derive the profiles shown in Figs. 2, 3, and 8.

We identified the following XSPEC model as best general description of the data (unless stated otherwise for tests), TBABS (APEC+POW+GAUSS+GAUSS)+TBABS APEC where the first foreground absorption (Tbabs model) is the absorption towards the GC, the first apec model is the intrinsic  $\sim 1$  keV plasma at the GC, the pow and the two gauss models describe the powerlaw and two narrow Gaussian lines at 6.4 and 6.7 keV caused by unresolved point sources around the GC and non-thermal emission<sup>1</sup> (the photon index of the power law was fixed to  $\Gamma = 1.8$ ). The second apec model with lower foreground absorption ( $0.7 \times 10^{22} \text{ cm}^{-2}$ ) and a temperature of about 0.2 keV describes a "foreground" emission (i.e., between the observer and the GC, e.g., such as the contribution from the local bubble) that was observationally chosen to fit the data. Throughout this work we used the apec model for collisionally-ionised diffuse gas, which is based on the ATOMDB code v3.0.7<sup>42</sup>. Uncertainties are quoted on the  $1\sigma$  level unless stated otherwise. Abundances are according to Solar abundances as from <sup>43</sup>. The distance to the GC was assumed to be 8 kpc<sup>44</sup>.

The profiles shown in Figs. 2, 3, and 8 are derived from the best fit values of the apec model to the intrinsic  $\sim 1$  keV plasma component at the GC. The free fit parameters are the plasma temperature (T [keV]) and the model normalization ( $\eta$  [ $\text{cm}^{-5}$ ]). The surface brightness profiles are given as  $\eta \text{ arcmin}^{-2}$ . Density (n [ $\text{cm}^{-3}$ ]) and pressure (P [keV  $\text{cm}^{-3}$ ]) were derived assuming full ionization with 10 per cent helium and 90 per cent hydrogen (i.e.  $n_e \sim 1.2n_p$ ),

$$n = \sqrt{\eta \times \frac{19.3 \pi D_A^2}{V}} \quad (1)$$

$$P = T \times n \quad (2)$$

where  $D_A$  is the distance to the source in cm and  $V$  is the assumed volume in  $\text{cm}^3$ . The volume was calculated as the extraction surface area times the assumed depth. For the  $\pm 15$  pc lobes we assumed a constant depth of 15 pc. For the remaining diffuse emission, we assumed a uniform depth of 150 pc, as suggested by the size of the Chimneys. A caveat of this approach is that the density beyond the Chimneys, at the foot of the Fermi-Bubbles, might be overestimated by a large factor, because that emission probably comes from a much larger volume. Indeed, if we assume a depth of 1.5 kpc for the high latitude emission, the expected particle density would drop to  $\sim 10^{-2} \text{ cm}^{-3}$ .

Comparing the surface brightness of the Fermi-bubble X-ray counterparts in *ROSAT* images with the high latitude emission observed with *XMM-Newton*, we found good agreement. The photon count rate in a *ROSAT* 1-2 keV (assuming  $\sim 60 \text{ cm}^2$  effective area) mosaic image (Fig. 5) and in the *XMM-Newton* image ( $\sim 1500 \text{ cm}^2$ ) of the same band are consistent at  $\sim 3 \times 10^{-6} \text{ s}^{-1} \text{ cm}^{-2} \text{ arcmin}^{-2}$  (1-2 keV).

**Other sources powering Sgr A's bipolar lobes** In the main article we suggested that Sgr A's bipolar lobes are primarily powered by supernovae explosions and tidal disruption events. However, this does not exclude that other processes might provide a contribution in powering such features.

For example, can the current activity of Sgr A\* inflate the  $\pm 15$  pc Sgr A's bipolar lobes<sup>30</sup>? Studies of clusters of galaxies demonstrate that supermassive black holes accreting at low Edding-

ton rates do generate outflows that inflate bubbles into the intra-cluster medium and have kinetic luminosities orders of magnitude larger than the instantaneous radiative power of these BH<sup>45,46</sup>. For Sgr A\* the quiescent radiative luminosity  $\sim 10^{36}$  erg s<sup>-1</sup>, when expressed in Eddington units, is even lower than for the black holes in galaxy clusters, firmly placing this object deep into a very low-luminosity regime<sup>47</sup>. It is plausible that in this regime the outflow power can exceed the radiative luminosity by a large factor, opening a possibility that Sgr A\* could provide the mechanical luminosity, needed to power the  $\pm 15$  pc Sgr A bipolar lobes, even without invoking additional tidal disruption-like major outbursts.

**Uncertainty related with the unknown filling factor and abundances** The X-ray morphologies of all structures seen in *ROSAT*, *XMM-Newton* and *Chandra* images are very complicated with signs of edge-brightening. It is plausible that the X-ray-emitting gas is not volume filling, but represents patches of denser gas interacting with an outflow, as suggested by many simulations that involve rapid expansion and adiabatic cooling of matter in the outflow<sup>11</sup>. We nevertheless assume in the main paper the volume filling factor  $f = 1$ , to derive the gas density in the observed structures and estimate their total energy content. For  $f < 1$ , the recovered density scales as  $n_{obs} \propto n_{true} f^{1/2}$ . Assuming that the energy density is uniform over the structure (in the longitudinal direction), the estimated total energy will be also lower than the true one by a factor  $f^{1/2}$  and therefore should be treated as a lower limit.

Throughout the paper, we assume Solar abundances of the X-ray emitting plasma. This assumption is performed in order to avoid spurious degeneracies between the fitted parameters. We note that the X-ray emitting plasma in the plane, within the central molecular zone, has Solar

or slightly super-Solar metallicities<sup>10,7,48</sup>. The metallicity is expected to drop with latitude. Indeed, the halo metallicity is expected to be significantly lower than Solar, with metallicities of the X-ray emitting plasma of the order of  $\sim 0.3$  Solar, inside the FB<sup>9,26</sup>. To quantify the consequences of this assumption, we fitted one of the *XMM-Newton* spectra of the northern Chimney changing the assumed metallicity from 1.5 to 0.3 Solar. We observed that the best fit temperature and emissivity changed by  $\sim 5$  and  $\sim 10$  %, respectively.

Figure 4: X-ray emission from the central degrees of the Milky Way. Bright X-ray emission traces the coherent edge brightened shell-like feature, dubbed northern Chimney, located north of Sgr A\* and characterised by a diameter of  $\sim 160$  pc. On the opposite side, the southern Chimney appears as a bright linear feature. Bright X-ray emission is observed at high latitude ( $|b| \gtrsim 1^\circ$ ), corresponding to the X-ray counterparts of the *Fermi* bubble. The magenta dashed line intersects both Chimneys, passing through Sgr A\*. The map shows the X-ray emissivity within the 1.5-2.6 keV energy band. Point sources have been removed. Larger circles have been excised to remove the dust scattering haloes around bright sources.

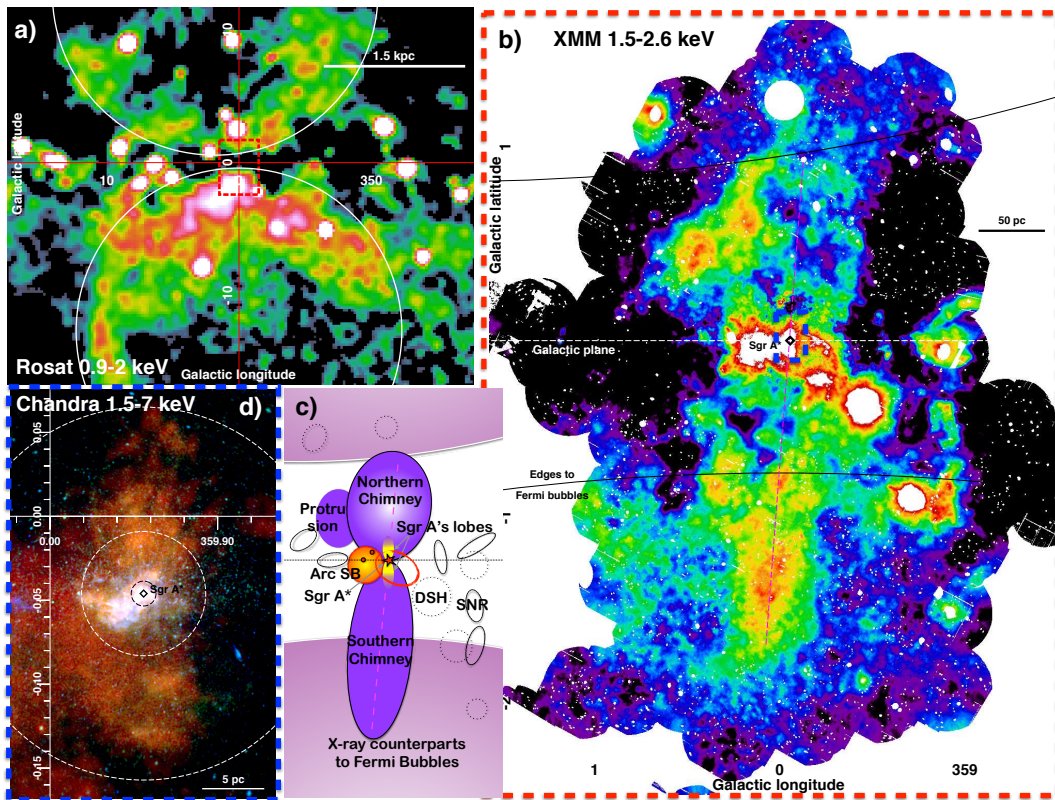

Figure 5: (*Panel a*) ROSAT (0.9-2 keV energy band) large scale map of the GC. The X-ray counterparts of the *Fermi* bubbles are strong X-ray emitters. The edges (white ellipses) are clearly detected on scales of several degrees, while they become confused (because of the short exposure of 200-300 s and soft X-ray energy band) close to the plane. The red dashed line indicates the *XMM-Newton* area covered by our survey. (*Panel b*) *XMM-Newton* map zooming into the central degrees of the Milky Way. The magenta dashed line intersects both Chimneys, passing through Sgr A\*. The map shows the X-ray emissivity within the 1.5-2.6 keV energy band (see Fig. 4). (*Panel c*) Schematic view of the main diffuse X-ray emitting features within the central  $\sim 500$  pc from Sgr A\*. The red star and the yellow ellipses indicate the position of Sgr A\* and of Sgr A's  $\pm 15$  pc bipolar lobes. The large violet ellipses indicate the location and extension of the X-ray counterpart of the GCL with shell like morphology (northern Chimney), of its eastern protrusion and of its roughly symmetric southern counterpart (southern Chimney). The orange filled ellipse, the two red circles and the red ellipse indicate the location of the Arc super-bubble, the Quintuplet and Arches clusters and the super-bubble candidate G359.77-0.09<sup>7</sup>. The pink regions indicate the location of the edges to the *Fermi* bubbles. The dotted circles and solid ellipses indicate the position of bright X-ray sources with intense dust scattering halos and known supernova remnants. (*Panel d*) *Chandra* RGB map zooming into the central tens of parsecs of the Galaxy. The  $\pm 15$  pc lobes are clearly visible in orange colour. The dashed circles have radii of 1, 5, and 15 pc.

Figure 6: Continuum subtracted S XV line emission. The map highlights sources characterised by bright soft X-ray emission lines, such as diffuse thermally emitting plasma. On the other hand, point sources and dust scattering halos are efficiently removed. The white dashed tilted line indicates a linear ridge,  $\sim 450$  pc long, that appears to run west of the Chimneys.

Figure 7: Chandra 1-2 keV map of the Galactic centre. The same structures seen in the *XMM-Newton* 1.5-2.6 keV image (Fig. 4, footprint indicated by red dashed box) are observed also in the shallower *Chandra* image. Despite the 1-2 keV band map is more affected by neutral absorption towards the plane, compared with the 1.5-2.6 keV band (Fig. 4), we display it here in order to emphasise the residual high latitude emission (e.g., inside the *Fermi* bubbles).

Figure 8: From top to bottom: temperature; density and pressure profiles as a function of longitude cutting through the northern and southern Chimneys at latitudes  $b \sim 0.7^\circ$  and  $b \sim -1.2^\circ$  (see Fig. 10). Positive values indicate Galactic West (West is right as in an image in Galactic coordinates). Black squares and red circles indicate the longitudinal cut through the northern and southern Chimneys, respectively. The densities have been estimated assuming a volume  $V = PA^{3/2}$ , where PA stands for the projected area.

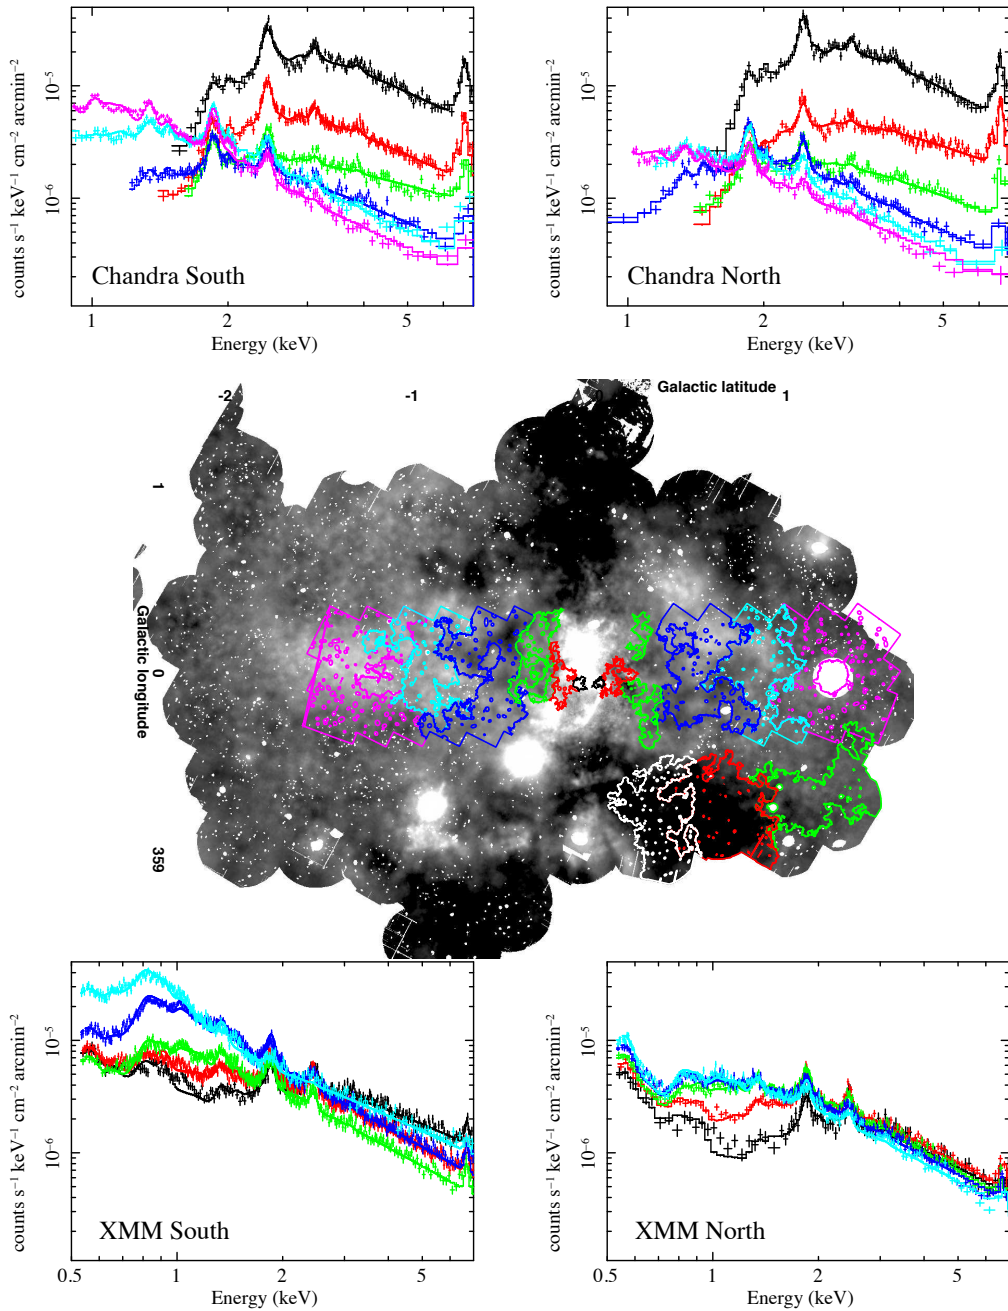

Figure 9: (*Top panels*) *Chandra* spectra used to derive the latitudinal profiles at  $l = 0^\circ$  and shown in Fig. 2 for the southern (left) and northern (right) sides, respectively. (*Central panel*) *XMM-Newton* 1.5-2.6 keV emission map in greyscale, showing the extraction areas of the *Chandra* spectra used to derive the latitudinal profiles at  $l = 0^\circ$ , with colours corresponding to those of the spectra. The areas at  $l \sim -0.7^\circ$  indicate the extraction regions of the spectra used to derive the grey constraints in Fig. 2. (*Bottom panel*) *XMM-Newton* spectra used to derive the latitudinal profiles of the diffuse emission in Fig. 2.

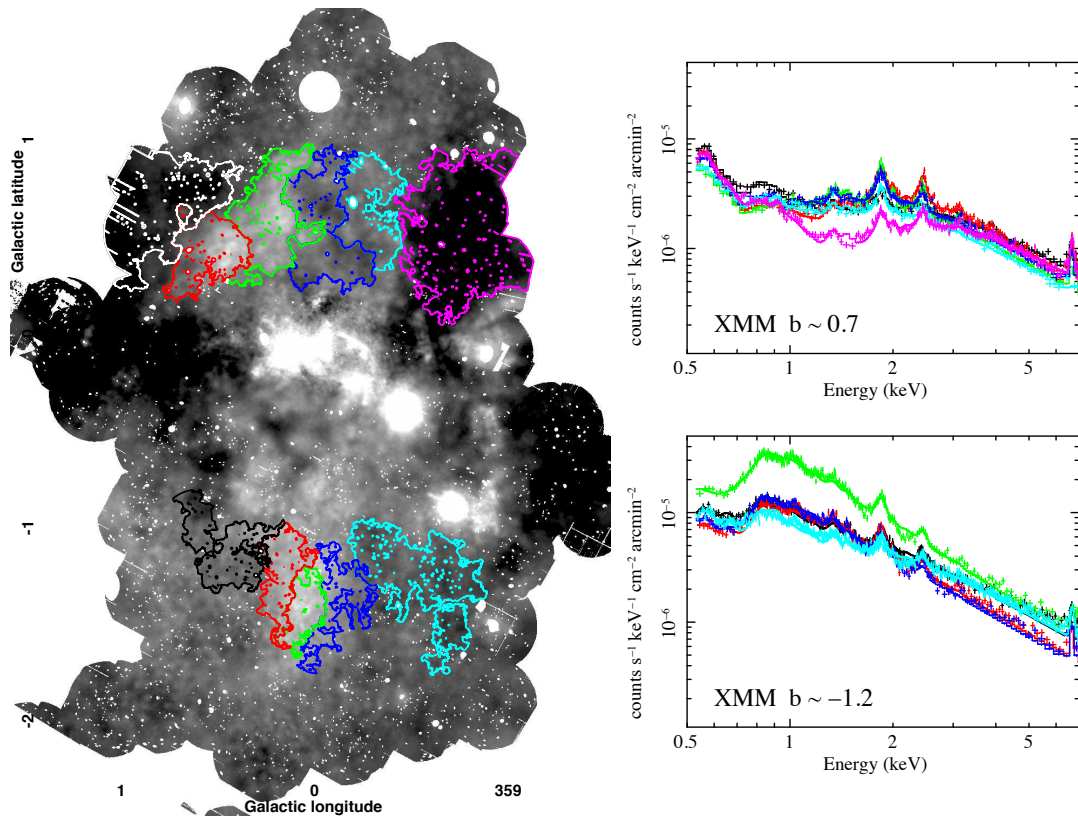

Figure 10: (*Top panels*) XMM-Newton spectra used to measure the longitudinal profiles shown in Fig. 8. (*Bottom panel*) XMM-Newton 1.5-2.6 keV map displaying the regions used to extract the spectra corresponding to a longitudinal cut through the northern shell (at  $b \sim 0.7^\circ$ ) and through the jet-like feature (at  $b \sim -1.2^\circ$ ).
