Abstract

Stardust grains that originated in ancient stars and supernovae are recovered from meteorites and carry the detailed composition of their astronomical sites of origin. We present evidence that the majority of large (μm -sized) meteoritic silicon carbide (SiC) grains formed in C-rich asymptotic giant branch (AGB) stars that were more metal-rich than the Sun. In the framework of the slow neutron captures (the s process) that occur in AGB stars, the lower-than-solar $^{88}\text{Sr}/^{86}\text{Sr}$ isotopic ratios measured in the large SiC grains can only be accompanied by Ce/Y elemental ratios that are also lower than solar and predominately observed in metal-rich barium stars—the binary companions of AGB stars. Such an origin suggests that these large grains represent the material from high-metallicity AGB stars needed to explain the s -process nucleosynthesis variations observed in bulk meteorites. In the outflows of metal-rich, C-rich AGB stars, SiC grains are predicted to be small ($\simeq 0.2 \mu\text{m}$); large ($\simeq \mu\text{m}$ -sized) SiC grains can grow if the number of dust seeds is 2–3 orders of magnitude lower than the standard value of 10^{-13} times the number of H atoms. We therefore predict that with increasing metallicity, the number of dust seeds might decrease, resulting in the production of larger SiC grains.

1. Introduction

Stellar grains (“stardust”) are recovered from primitive meteorites, where they were incorporated 4.6 Gyr ago during the formation of the solar system after interstellar travel from their stellar sites of origin—mostly asymptotic giant branch (AGB) stars and core-collapse supernovae—to the molecular cloud where the Sun formed (Zinner 2014; Nittler & Ciesla 2016). Since their discovery more than 30 yr ago, these grains have provided powerful constraints for the modeling of nucleosynthesis in stars and supernovae. Recently, it has also become evident that the fingerprint of the almost pure nucleosynthetic signatures carried by these grains into different solar system bodies can be exploited to understand the evolution of the protoplanetary disk and the formation of the planets (see, e.g., Dauphas et al. 2004; Poole et al. 2017; Burkhardt et al. 2019; Nanne et al. 2019; Stephan et al. 2019; Ek et al. 2020).

Both O-rich (such as Al_2O_3 , MgAl_2O_4 , and silicates) and C-rich stardust has been recovered, among which the most widely and accurately investigated are silicon carbide (SiC) grains (Bernatowicz et al. 1987). This is due to their sizes, which can be large enough (up to a few to tens of μm) for single-grain analysis, and because it is easier to recover them compared to the other phases. On top of the main elements, Si and C, these grains contain enough other trace elements to provide very accurate snapshots of the composition of their parent stars, from N, Ne, Mg, S, Ca, Ti, Fe, and Ni to rare elements heavier than Fe, such as Sr, Zr, Mo, Ru, Ba, Eu, W, and Hf (see, e.g., Lewis et al. 1990, 1994; Hoppe et al. 1994; Savina et al. 2004; Ávila et al. 2012, 2013; Liu et al. 2014, 2015; Trappitsch et al. 2018).

It was recognized early that the vast majority of these grains originate from a population of AGB stars of low mass, typically in the range $1.5\text{--}4 M_{\odot}$. These stars reach the condition $C > O$ required to condense SiC in their envelopes thanks to the mixing (third dredge-up (TDU)) episodes that carry to the stellar surface C produced by He burning in the deep He-rich

¹⁹ NuGrid Collaboration, <http://www.NuGridstars.org>.

intershell layer between the H- and He-burning shells (see Karakas & Lattanzio 2014, for a review). Evidence for this origin lies in the $^{13}\text{C}/^{12}\text{C}$ ratio distribution of the grains, which is similar to that observed in C-rich AGB stars (Hoppe & Ott 1997), and the fact that the grains are strongly enriched in ^{22}Ne , another typical product of He burning (Gallino et al. 1990), and in the isotopes of elements heavier than Fe that are produced by the slow neutron-capture process (the *s* process) that occurs in the intershell of AGB stars (Lugaro et al. 2003). However, the exact mass and metallicity range of the AGB parent stars of stardust SiC has so far been difficult to determine accurately. The vast majority ($\gtrsim 90\%$) of the grains (the “mainstream” SiC grains) are generally believed to have originated in C-rich AGB stars of metallicity around solar, while an origin in AGB stars of lower metallicities has been attributed to the less abundant populations Y and Z ($\sim 1\%$ of all SiC each; Hoppe et al. 1997; Amari et al. 2001a; Zinner et al. 2006), although there are some inconsistencies with such an explanation (see, e.g., Lewis et al. 2013; Liu et al. 2019). The remaining SiC grains mostly belong to population A + B, of unclear origin (Amari et al. 2001b; Liu et al. 2017a, 2017b, 2018c), and population X from core-collapse supernovae (e.g., Liu et al. 2018b).

Here we focus on the mainstream SiC grains, which are by far the most abundant. While high-precision data are available for such grains, unambiguous identification of their exact AGB origin is hampered by the fact that various uncertainties related to the modeling of stellar physical processes can mimic variations in stellar mass and metallicity. This results in a degeneracy of the nucleosynthetic solutions that can be found to match the same observed composition. Stellar physics uncertainties include the treatment of convective mixing in all phases of the evolution, stellar rotation, the rate of mass loss from the stellar surface, and the mixing processes leading to the dredge-up of carbon, ^{22}Ne , and *s*-process elements to the stellar surface and to the production of a region rich in the main neutron source, ^{13}C nuclei (the ^{13}C pocket; see discussion in, e.g., Cristallo et al. 2009; Piersanti et al. 2013; Karakas & Lugaro 2016; Trippella et al. 2016; Liu et al. 2018a; Battino et al. 2019; den Hartogh et al. 2019). Therefore, in spite of their outstandingly high-precision isotopic measurements of SiC, stardust cannot yet be used to strongly constrain uncertainties in stellar modeling (as we will discuss in Section 4).

The best approach to identifying the parent stars of the grains would instead be to compare the stardust data directly to the abundances derived from the spectra of AGB stars and their binary companions for which we know the stellar mass and metallicity. Recently, a consistent spectroscopic data set for a large (≈ 180) sample of giant barium (Ba) stars, i.e., stars that accreted *s*-process elements from an AGB companion, has become available (de Castro et al. 2016) with improved calculations of the uncertainties (Cseh et al. 2018). This new data set has already allowed us to determine, for example, that stellar metallicity is the main determinant of the distribution of the elements heavier than Fe in AGB stars and that other effects, such as rotation, should play a secondary role (Cseh et al. 2018); this is in agreement with asteroseismology observations (den Hartogh et al. 2019). Here we aim to exploit the Ba-star data to more accurately determine the origin of stardust SiC grains.

2. Observational Data

Analysis of stellar spectra mostly provides *s*-process constraints in terms of elemental abundances; analysis of stardust grains instead mostly provides *s*-process constraints in terms of isotopic ratios. This is because elemental abundances in stardust SiC are predominantly controlled by the chemistry of dust formation rather than nucleosynthesis. Therefore, we need a method to relate the elemental abundance ratios observed in *s*-process-enhanced stars to the isotopic ratio measured in SiC grains. To this aim, we consider two main *s*-process observable ratios, one related to Ba stars (and inherited from their AGB companions) and one related to SiC stardust. The AGB parent stars of the SiC grains correspond to stars born between 5 and 10 Gyr ago, as obtained by summing (i) the age of the Sun of 4.6 Gyr, (ii) the interstellar lifetime of the grains (between 0.3 and 3 Gyr; Heck et al. 2020), and (iii) the lifetime of a star of mass between 1.5 and $4 M_{\odot}$, believed to become C-rich at solar metallicity, roughly between 0.2 and 3 Gyr. The Ba-star AGB companions probably represent a younger population, since these stars are not required to have evolved to the AGB phase before the formation of the Sun. Their corresponding ages would have been roughly between 0.2 and 3 Gyr, plus the time elapsed since the mass transfer event that produced the Ba stars, which is unknown. In any case, the main features (mass and metallicity) of the AGB parent stars of the SiC grains are comparable to those of the Ba-star AGB companions because we do not expect major variations in the initial mass function over the past 8 Gyr, nor do we observe major changes in the metallicity distribution; see, e.g., Figure 16 of Casagrande et al. (2011) and Figure 10 of Hayden et al. (2015).

2.1. The $[\text{Ce}/\text{Y}]$ Ratio in Ba Stars

For Ba stars, we consider the $[\text{Ce}/\text{Y}]^{20}$ ratio derived from spectroscopic observations because Ce and Y are *s*-process elements belonging to the *s*-process second (isotopes with magic number of neutrons 82) and first (magic number of 50) peaks, respectively. This means that their relative abundances are a measure of the number of neutrons captured per Fe seed during the *s* process. The $[\text{Ce}/\text{Y}]$ ratios for the large sample of Ba stars from Pereira et al. (2011) and de Castro et al. (2016) are plotted against metallicity in the top panel of Figure 1, with metallicities ranging from roughly 1/4 of solar ($[\text{Fe}/\text{H}] = -0.6$) to twice solar ($[\text{Fe}/\text{H}] = +0.3$). The $[\text{Ce}/\text{Y}]$ errors were calculated for all of the sample stars as described in Cseh et al. (2018). Observationally, the main trend of the $[\text{Ce}/\text{Y}]$ ratio in Ba stars is to decrease with increasing metallicity. This agrees with the main feature of low-mass AGB *s*-process models (some examples of which are shown in the top panel of Figure 1), which is that the main neutron source, ^{13}C , does not depend on the metallicity, while the main neutron absorber, Fe, obviously increases with increasing metallicity (Clayton 1988; Gallino et al. 1998). This results in a decrease of the number of neutrons captured per Fe seed at higher metallicity, because the number of neutrons produced remains the same (as the number of ^{13}C nuclei), but as Fe increases, for each Fe atom, there are fewer neutrons available to capture. Overall, at higher metallicity, the final atomic mass reached by the neutron-capture process is lower, and it is more difficult to reach the

²⁰ Throughout the paper, to express elemental ratios, we use the square bracket notation, which represents the \log_{10} of the observed abundance ratios relative to the solar ratio, equal to zero by definition.

Figure 1. Top panel: $[\text{Ce}/\text{Y}]$ ratio observed in Ba stars as a function of the metallicity $[\text{Fe}/\text{H}]$ from Pereira et al. (2011) and de Castro et al. (2016). The data points are semitransparent; therefore, they appear darker in denser regions of the plot. The colored lines show the results from a selection of the AGB models presented in Figure 2 (with the same symbols and colors) as examples of stellar model predictions (see also Cseh et al. 2018). Bottom panel: distribution of Ba stars with $[\text{Ce}/\text{Y}] < 0$ representing the ratio of the number of stars with negative $[\text{Ce}/\text{Y}]$ in each metallicity bin to the total number of stars with negative $[\text{Ce}/\text{Y}]$, divided by the ratio of the number of stars in each bin to the total number of stars (i.e., $\frac{\text{negative in bin}}{\text{total negative}} / \frac{\text{total in bin}}{\text{total}}$). The error bars on the bins are calculated by applying the bootstrap method (see Section 3 for details).

second s -process peak. This leads to higher Sr, Y, and Zr abundances as compared to Ba, La, and Ce. The same trend shown by $[\text{Ce}/\text{Y}]$ in Figure 1 is also shown by other second-to-first-peak elemental ratios. Here we decided to consider $[\text{Ce}/\text{Y}]$ because it shows the smallest uncertainty in the observational data (Cseh et al. 2018).

2.2. The $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ Ratio in Stardust SiC Grains

For SiC grains, high-precision isotopic data are available that accurately reflect the composition of the gas from which the grains formed. Here we chose to consider the $^{88}\text{Sr}/^{86}\text{Sr}$ ratio and will express all isotopic ratios throughout the paper in the form of δ values, i.e., permil variations with respect to the solar ratio, which is zero by definition in the δ value. Positive/negative δ values indicate ratios higher/lower than solar. For example, $\delta(^{88}\text{Sr}/^{86}\text{Sr}) = +500$ means that the measured $^{88}\text{Sr}/^{86}\text{Sr}$ ratio is 50% higher than the solar ratio, while $\delta(^{88}\text{Sr}/^{86}\text{Sr}) = -500$ means that the measured $^{88}\text{Sr}/^{86}\text{Sr}$ ratio is 0.5 of the solar ratio. We selected the $^{88}\text{Sr}/^{86}\text{Sr}$ ratio because ^{88}Sr is located on the first s -process peak and $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ can vary substantially from negative to positive values when increasing the number of neutron captures per Fe seed, similar to the $[\text{Ce}/\text{Y}]$ ratio. Also, increasing the neutron density has the effect of increasing the value of $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ because the branching

points at ^{85}Kr and ^{86}Rb can open when the neutron density reaches above 5×10^8 and 10^9 n cm^{-3} , respectively, therefore bypassing the production of ^{86}Sr (see, e.g., van Raai et al. 2012; Bisterzo et al. 2015).²¹

Since the 1990s, a large fraction of the meteoritic SiC grain data has been reported in the literature from experiments on stardust isolated by acid dissolution of the Murchison CM2 meteorite, specifically from the K series extracted by Amari et al. (1994). These authors used centrifugation to finely separate SiC grains of different size ranges and named the different samples KJA to KJH in order of increasing grain size, as indicated in Table 1. The first analyses of the isotopic composition of elements heavier than iron present in SiC in trace amounts were possible only on bulk samples, i.e., on large (millions of grains) collections of SiC of a given fraction (i.e., size). With the development of resonant ionization mass spectrometry (RIMS; Savina et al. 2003; Stephan et al. 2016), it has become possible to analyze with statistical significance the composition of trace elements in single SiC grains. The RIMS high-precision data provide the composition of each AGB parent star of each single grain, rather than the average over a whole population of AGB parent stars, as for the bulk analysis. However, only relatively large grains ($>1 \mu\text{m}$) contain enough atoms to be analyzed individually via RIMS.

Interestingly, it was noticed since the first analyses that the average isotopic composition of several elements in the SiC grains varies with the grain size. This indicates that nucleosynthetic and dust-growth processes somewhat correlate in AGB stars, possibly as function of mass and/or metallicity.²² In the case of Sr, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ varies from positive in the KJB and KJC size fractions to negative in KJD and KJE (Table 1), with an overall variation of 6% (Podosek et al. 2004). The RIMS measurements of individual 1–3 μm SiC grains are mostly located in the region between -200 and zero (Liu et al. 2015, 2018a).

For $\delta(^{138}\text{Ba}/^{136}\text{Ba})$, a decreasing trend was also found moving from KJC to KJE (Table 1). Because both $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ and $\delta(^{138}\text{Ba}/^{136}\text{Ba})$ involve a nucleus with a magic number of neutrons, it was recognized early that the number of neutrons captured per Fe seed should play a role in such variations, with the parent stars of the larger grains somehow experiencing a lower number of neutrons captured per Fe seed (see also discussion in Ott & Begemann 1990; Zinner et al. 1991; Gallino et al. 1997). With respect to the data from single KJG grains, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ shows more significant variations than Ba: in the large (KJE and KJG) grains, it is mostly negative, while the bulk value on the small grains (KJB) is clearly positive. For $\delta(^{138}\text{Ba}/^{136}\text{Ba})$, the large (KJG) grains cover the whole range observed in all of the different smaller grain size fractions (KJC

²¹ We note that the contribution of the weak s process in massive stars to the Sr in the solar system is too uncertain (see, e.g., Figure 11 of Pignatari et al. 2010) to independently constrain the $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ from the AGB stars that synthesized the s -process solar system abundances. In general, if the contribution to ^{86}Sr from the weak s process was significant, then the AGB stars that synthesized the s -process solar system abundances must have produced, on average, a positive $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ value to counterbalance the effect of the s process in massive stars. If, instead, the contribution to ^{86}Sr from massive stars is marginal or ^{88}Sr is also produced significantly (which may be the case when considering rotation in massive stars; e.g., Prantzos et al. 2018), then AGB stars must have produced, on average, a negative or null $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ value.

²² One more complex case is that of the noble gas Kr, where variations in isotopic ratios as a function of the grain size are also impacted by the velocity of the wind that implanted such Kr atoms in preexisting grains, producing different results between the slow AGB wind and the fast post-AGB wind (Lewis et al. 1994; Verchovsky et al. 2004; Lugaro et al. 2017).

Table 1
Mass-weighted Mean Particle Size and Abundance

Fraction	Size ^a (μm)	Abundance (ppm)	$\delta(^{29}\text{Si}/^{28}\text{Si})^{\text{b}}$	$\delta(^{88}\text{Sr}/^{86}\text{Sr})^{\text{c}}$	$\delta(^{138}\text{Ba}/^{136}\text{Ba})^{\text{d}}$
KJA	0.24–0.65	0.25	22.2 ± 1.6

KJC	0.42–1.02	1.11	29.0 ± 2.1	3 ± 14	-319 ± 9
KJD	0.54–1.23	1.21	27.0 ± 2.5	-18 ± 18	-321 ± 10
KJE	0.70–1.65	0.97	31.8 ± 3.0	-40 ± 15	-348 ± 10
			$39.7 \pm 3.6^{\text{e}}$		
KJG	2.1–4.5	0.36	50.0 ± 5.6	(0 to -200^{f})	(-200 to -400^{f})

Notes. Fractions KJF and KJH also exist, but no such data are available. All of the data represent the composition measured by analyzing millions of grains together (i.e., in bulk), except in the case of the large (KJG) grains for which data for single grains are also available. The latter are indicated in parentheses as reminders that they should not be quantitatively compared to the bulk data.

In parts per million by mass (ppm) for the KJ SiC grain fractions extracted from the Murchison meteorite (Amari et al. 1994) for which data are available for $\delta(^{29}\text{Si}/^{28}\text{Si})$, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$, and/or $\delta(^{138}\text{Ba}/^{136}\text{Ba})$

to KJE; see Table 1). We note that terrestrial contamination could have affected all of the SiC measurements and would have shifted the measured isotopic ratios toward the solar values relative to the true compositions, and the amount of contamination could potentially depend on the grain size. It is thus possible on the one hand that the solar $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ value reported for the KJC bulk measurement may be an artifact, and on the other hand that the true $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ for bulk KJB may be more positive than reported. The latter possibility would strengthen the conclusion that smaller and larger grains have positive and negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ values, respectively.

As mentioned above, the neutron density can also have a role in increasing $\delta(^{88}\text{Sr}/^{86}\text{Sr})$, while it does not affect $\delta(^{138}\text{Ba}/^{136}\text{Ba})$, since there are no branching points active in AGB stars that can modify the relative isotopic abundances of ^{138}Ba and ^{136}Ba . However, the effect of the neutron density on $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ is predicted to be of second order relative to the effect of the number of neutron captures per Fe seed. Considering, for example, Figures 4 and 15 of Lugaro et al. (2003), where the effect of branching points was deliberately switched off, the variations in $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ due to the variations in the number of neutron captures per Fe seed explored in that paper cover a range of 600 permil (roughly -400 to -200), while the variations in $\delta(^{138}\text{Ba}/^{136}\text{Ba})$ due to the same variations in the number of neutron captures per Fe seed cover a much smaller range of 250 permil (roughly -350 to -100). Therefore, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ is a better indicator of the number of neutron captures per Fe seed than $\delta(^{138}\text{Ba}/^{136}\text{Ba})$ in the metallicity range of solar to twice solar considered here and relevant for the mainstream SiC grains.²³ Therefore, hereafter, we focus on the $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ variations, which are the most significant.

²³ At lower metallicities, a significant effect of the higher neutron captures per Fe seed is predicted on $\delta(^{138}\text{Ba}/^{136}\text{Ba})$, which also increases to positive values as the neutron captures per Fe seed increase. For example, $\delta(^{138}\text{Ba}/^{136}\text{Ba}) = 577$ for a $3 M_{\odot}$ model of $Z = 0.0028$ from Karakas et al. (2018) and -24 and 719 for $3 M_{\odot}$ models of $Z = 0.008$ and 0.003 , respectively, from the FRUITY database. This is because at such metallicities, the range of neutron captures per Fe seed experienced by the AGB material corresponds to that where the second *s*-process peak elements are more significantly produced, while the range we consider in this paper corresponds to that where the first *s*-process peak elements are more significantly produced (see, e.g., Figure 1 of Travaglio et al. 2004).

3. Translating Stardust $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ Ratios into Ba-star [Ce/Y] Ratios

3.1. Parametric Models (Black Solid Line in Figure 2)

To compare the SiC to the Ba-star data and identify the parent stars of the grains, we need to investigate the correlation between $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ and [Ce/Y] predicted by models of the *s* process. The more general the model is, the more robust the prediction of such a correlation; therefore, we start considering a parametric model of the *s* process, which is not affected by all of the stellar model uncertainties mentioned in the Introduction. In Figure 2, we plot the results of a parametric model of *s*-process nucleosynthesis calculated by feeding a constant neutron density to a nuclear network with initial low-metallicity abundance distribution using the NucNetTools (Meyer 2012) and the JINA Reaclib database (Cyburt et al. 2010; more information and details on these models can be found in Hampel et al. 2016, 2019).

We set the constant neutron density to 10^7 neutrons cm^{-3} and run the simulations for 60,000 yr, which are typical orders of magnitude for the neutron flux in the ^{13}C pocket. If we increase the value of the neutron density, the branching points at ^{85}Kr and ^{86}Rb can activate, and $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ may increase. For example, for a neutron density of 10^8 n cm^{-3} , the value of $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ in the section of the black line located in the top right quadrant of Figure 2 increases and reaches $\simeq 12,000$. In relation to this, it should be considered that in models of AGB stars with masses typically higher than $3 M_{\odot}$, the activation of the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction during recurrent episodes of He burning may produce a further neutron burst with higher neutron densities than those within the ^{13}C pocket, potentially activating the branching points at ^{85}Kr and ^{86}Rb and increasing the value of $\delta(^{88}\text{Sr}/^{86}\text{Sr})$. This neutron burst provides a small amount of neutrons and only contributes to the production of the first-peak *s*-process elements, at least in AGB stars of metallicity around solar, potentially marginally decreasing the [Ce/Y] ratio. Overall, an upward shift of 300–400 in $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ (compare Figures 3 and 4 of Lugaro et al. 2003) and a decrease in [Ce/Y] by up to -0.1 dex (see discussion in Cseh et al. 2018) would qualitatively account for the upper limit of

Figure 2. The $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ as a function of the $[\text{Ce}/\text{Y}]$ ratio as predicted by a parametric model of neutron captures (black line). The initial abundances are scaled solar (i.e., the origin in the plot). Also shown by the colored symbols are predictions for the composition of the stellar surface at the end of the evolution from different sets of calculations of AGB stars of different initial masses (see legend). The same symbols of different sizes (connected by the solid colored lines) indicate different initial metallicities (in the range listed below for each set of models), with increasing symbol size representing increasing metallicity. As discussed in Section 2.1, the general trend is that higher-metallicity models typically predict lower $[\text{Ce}/\text{Y}]$ ratios. We include models from the FRUITY database (F; $Z = 0.003\text{--}0.03$ and where “rot” refers to models rotating with initial velocity 60 km s^{-1} and “tail” refers to models calculated with a different mixing profile leading to the formation of the ^{13}C pocket; Cristallo et al. 2015), the Monash code (M; $Z = 0.0028\text{--}0.03$ and with the standard extent of the partial mixing zone leading to the formation of the ^{13}C pocket as described in detail by Karakas & Lugaro 2016), and the NuGrid collaboration (N; $Z = 0.01\text{--}0.03$ and where “mix” represents the case where a constant slow mixing is included inside the ^{13}C pocket; Battino et al. 2019). Note that several other models were presented by Battino et al. (2019) to simulate potential mixing, but we do not include them in the figure for the sake of clarity, as they overlap with the plotted models. Examples of mixing lines between a selection of points from the parametric model and the solar composition are shown as dashed gray lines. All stellar model results are within such mixing lines.

the impact of the ^{22}Ne neutron burst on each of the points on the black line shown in Figure 2.

We set a temperature of $0.9 \times 10^8 \text{ K}$ and a density of 1000 g cm^{-3} , typical for the ^{13}C pocket. These specific choices do not have a significant effect on the final results, since we are not modeling the production of neutrons, and because neutron-capture reaction rates are typically only mildly dependent on the temperature, as the cross section is roughly proportional to the inverse of the velocity. We tested the impact of changing the temperature to $1.5 \times 10^8 \text{ K}$. This has a minor effect and only on the maximum $\delta(^{88}\text{Sr}/^{86}\text{Sr})$, which decreases from 3300 to roughly 2500.

Overall, the results from such a parametric model are controlled almost exclusively by the general properties of neutron-capture cross sections of the isotopes on the s -process path, specifically the presence of isotopes with magic numbers of neutrons. As time passes, more and more neutrons are fed into the network, and elements heavier than Fe are produced. Up to roughly 6000 yr (a neutron exposure of roughly 0.23 mbarn^{-1}), the first s -process peak elements represented by Y accumulate, since their magic number of neutrons results in relatively small neutron-capture cross sections (\simeq a few mbarn), and $[\text{Ce}/\text{Y}]$ is negative (bottom left quadrant of Figure 2). After this time, the abundance of ^{89}Y (the only stable isotope of Y) becomes large enough that this nucleus also starts capturing neutrons (top left quadrant of Figure 2), producing the second-peak elements (e.g., Ce). Eventually, $[\text{Ce}/\text{Y}]$ becomes positive

(top right quadrant of Figure 2). When Ce also becomes abundant enough to start capturing neutrons, the flux reaches the third peak at Pb (magic number of neutrons 126), and $[\text{Ce}/\text{Y}]$ settles on an equilibrium value of roughly $+0.8 \text{ dex}$.

At the same time, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ also evolves; it remains negative, together with the $[\text{Ce}/\text{Y}]$ ratio (bottom left quadrant of Figure 2), but becomes positive before the $[\text{Ce}/\text{Y}]$ ratio does (top left quadrant of Figure 2). When the $[\text{Ce}/\text{Y}]$ ratio reaches zero, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ is already $\sim +1000$. It reaches a maximum of roughly $+3300$ and then turns down to settle into the equilibrium value of roughly $+600$ (top left quadrant of Figure 2). A main result is that during the s process, negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ values are always accompanied by negative $[\text{Ce}/\text{Y}]$; i.e., there are no model predictions in the bottom right quadrant of Figure 2. This is simply because the second s -process peak at Ce is populated only after the first s -process peak at Sr, Y, and Zr. In other words, before the flux can proceed to the second peak, ^{88}Sr needs to be overproduced relative to ^{86}Sr , relative to solar. The potential activation of the ^{85}Kr and ^{86}Rb branching points mentioned above does not change this overall conclusion, since their only possible effect on the result of Figure 2 would be to increase the value of $\delta(^{88}\text{Sr}/^{86}\text{Sr})$.

3.2. Stellar Models (Symbols Connected by Colored Solid Lines in Figure 2)

While simple parametric neutron-capture models as presented in the previous section do not produce realistic

predictions for the surface composition of an AGB star, they still provide limits within which s -process stellar model predictions must be located. More realistic stellar models take into account several effects. First, the material in the He-rich intershell where the s process occurs is not the result of a single episode of neutron captures but rather the combination of many cycles of neutron captures. In fact, a ^{13}C pocket forms as a consequence of each TDU episode, of which there are typically 10–20 for C-rich stars in the low-mass AGB range considered here. Second, as mentioned at the start of the previous section, a marginal neutron flux can also occur within the recurrent convective instabilities during episodes of He burning in the intershell due to the activation of the ^{22}Ne reaction, and this can also affect the final intershell composition, particularly for the higher range of stellar masses when considering the effect of the neutron density and the related operation of the branching points at ^{85}Kr and ^{86}Rb on the $\delta(^{88}\text{Sr}/^{86}\text{Sr})$, discussed qualitatively in the previous section. Third, the material from the intershell is recursively carried to the stellar surface by the TDU and thus diluted with the envelope material.

Examples of predicted final surface compositions from three different sets of AGB stellar models are shown in Figure 2. As expected, the results from the stellar models lie on the intersection of mixing lines connecting the envelope abundances (with a distribution assumed to be close to solar) to compositions produced by different amounts of neutrons within the parametric models. In other words, the AGB s -process models are constrained to lie within the area covered by a “butterfly” shape produced by the parametric neutron-capture model and its mixing lines with solar composition. Only a few of the plotted stellar models reach the region of negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ observed in the large SiC grains (bottom left quadrant of Figure 2): the 3 and $3.5 M_{\odot}$ Monash models with $Z = 0.03$ and the $3 M_{\odot}$ NuGrid models of $Z = 0.03$ that include slow mixing in the ^{13}C pocket. Several more models with negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ presented by Liu et al. (2018a) support the results of Figure 2 (N. Liu 2020, personal communication).

Overall, the evidence from Figure 2 is that the negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ values observed in the large SiC grains are necessarily accompanied in their parent stars by negative $[\text{Ce}/\text{Y}]$. Therefore, to identify the parent stars of such grains, we need to search for the AGB stars that correspond to the companions of Ba stars with $[\text{Ce}/\text{Y}]$ lower than zero. Actually, this is a very conservative limit because the condition that $[\text{Ce}/\text{Y}]$ is lower than zero is necessary but not sufficient, given that it is possible to find neutron-capture results that show $[\text{Ce}/\text{Y}]$ lower than zero but $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ ratios higher than zero (top left quadrant of Figure 2).

3.3. Comparison to the Ba-star Sample

In the bottom panel of Figure 1, we show the normalized distribution of the number of Ba stars that show negative $[\text{Ce}/\text{Y}]$ for different metallicity bins. Each bin corresponds to 0.1 dex in metallicity, and the error bars on each bin were calculated using the bootstrap method (Efron 1979) as follows. We simulated 10,000 samples with 182 randomly chosen stars for each run by applying “random sampling with replacement” on the whole sample data set of 182 stars. This means that in each simulated sample, some stars can appear more than once, while others can be missing. For each selected star, the $[\text{Ce}/\text{Y}]$ ratio was chosen randomly from a normal distribution with a

width corresponding to the error bar of its given $[\text{Ce}/\text{Y}]$. Finally, we calculated the number of stars in each metallicity bin for all runs and the final error on the height of a bin as the standard deviation of the 10,000 runs.

The distribution of Ba stars with subsolar $[\text{Ce}/\text{Y}]$ ratios, i.e., the candidate parent stars of the large SiC grains, is heavily skewed toward stars of higher-than-solar metallicity, whose companions therefore appear to be the favored site of formation of the grains with negative $\delta(^{88}\text{Sr}/^{86}\text{Sr})$. For example, stars of metallicity from 1.6 to 2 times solar, i.e., $[\text{Fe}/\text{H}] = +0.2$ to $+0.3$, or $Z \simeq 0.02$ – 0.03 (using the solar metallicity of 0.014 from Asplund et al. 2009), are roughly 70% more likely to be the parent stars of the large grains than are stars from solar to 25% lower than solar metallicity (i.e., $[\text{Fe}/\text{H}] = -0.1$ to zero, or $Z \simeq 0.01$ – 0.014) and roughly 2.5 times more likely than stars with metallicities between 60% and 80% of solar (i.e., $[\text{Fe}/\text{H}] = -0.2$ to -0.1 , or $Z \simeq 0.009$ – 0.01). This estimate is a lower limit because, as the number of neutrons captured by the Fe seed increases, $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ becomes positive before the $[\text{Ce}/\text{Y}]$ ratio does (top left quadrant of Figure 2). Because both the observational and theoretical $[\text{Ce}/\text{Y}]$ versus $[\text{Fe}/\text{H}]$ trends show that the number of neutrons captured per Fe seed increases as the metallicity decreases, it is more likely that stars of lower rather than higher metallicity may have a negative $[\text{Ce}/\text{Y}]$ accompanied by a positive $\delta(^{88}\text{Sr}/^{86}\text{Sr})$.

3.4. Discussion and Further Predictions

In summary, it appears that the larger SiC grains should form in AGB stars of higher metallicity than the AGB sources of the smaller SiC grains. The Ba isotopic data from even larger SiC grains (7–58 μm from the LS + LU fractions of Amari et al. 1994) showing no Ba nucleosynthetic variation (Ávila et al. 2013) would then follow this trend and originate in AGB stars of even higher metallicity, such that the Ba isotopes remain mostly unaffected by s -process nucleosynthesis; however, they might still show variations in the composition of s -process elements belonging or close to the first s -process peak, e.g., Sr, Zr, and Mo.

The hypothesis that larger grains should come from more metal-rich AGB stars also predicts that the Si isotopic ratios should present some variations with the grain size due not to nucleosynthetic processes, as for Sr and Ba, but rather to galactic chemical evolution models, which predict that $\delta(^{29}\text{Si}/^{28}\text{Si})$ increases with metallicity (Timmes & Clayton 1996; Kobayashi et al. 2011b; Lewis et al. 2013). Even though heterogeneities in the interstellar medium could somewhat smear out such an increase (Lugaro et al. 1999; Nittler 2005), the expected trend is observed in the bulk data of SiC in grains of different sizes. These measurements show, in fact, that $\delta(^{29}\text{Si}/^{28}\text{Si})$ increases with grain size (Table 1). Among the Ti isotopic ratios, the least affected by neutron captures in AGB stars is $\delta(^{47}\text{Ti}/^{48}\text{Ti})$; therefore, this ratio should also carry the signature of the initial composition of the star. While an increase with grain size is observed from the KJA/KJB grains toward the KJF grains, KJG and KJH grains show a decline, although contamination problems could have affected the data (Amari et al. 2000).

In relation to the lighter elements C and N, interesting isotopic trends with grain size are present (Hoppe et al. 1994, 1996); however, they need to be discussed in a separate work because the isotopic compositions of these elements are affected by mixing processes in red giant and AGB stars, some of which are still not well understood (see, e.g., Karakas & Lattanzio 2014), and N may in some cases be severely affected

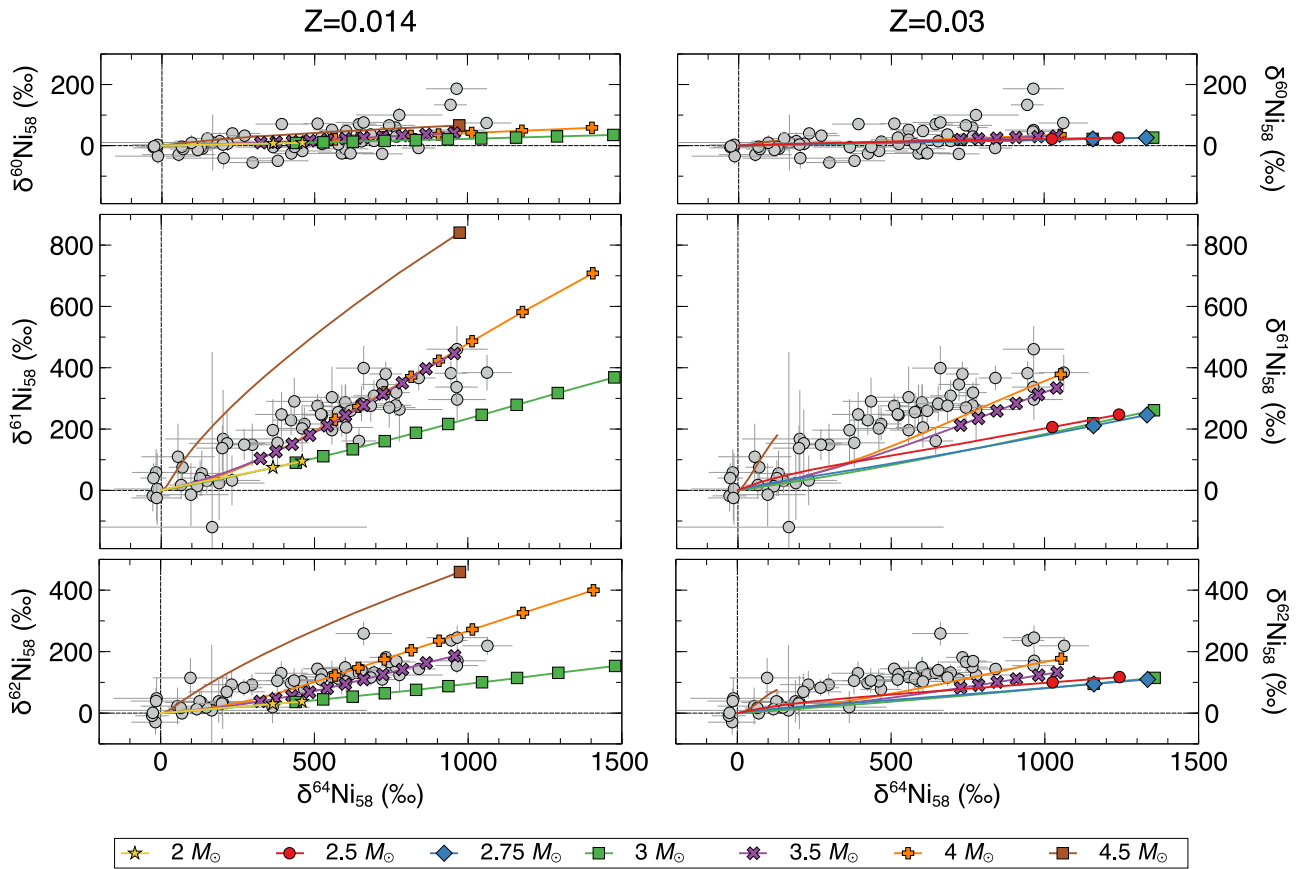

Figure 3. Comparison between single KJG SiC data from the Ni measurements of Trappitsch et al. (2018; gray symbols with 2σ error bars) and AGB stellar surface predictions from the models of Lugaro et al. (2018) at solar ($Z = 0.014$; left panels) and twice solar ($Z = 0.03$; right panel) metallicity and initial stellar masses between 2 and $4.5 M_{\odot}$. Different masses are represented by different colors, and symbols are plotted on top of the lines only when $C > O$, the condition of SiC formation, is achieved in the envelope. Note that in the axis labels of this and the following comparison figures, a shortened version of the δ notation is used; e.g., $\delta^{60}\text{Ni}_{58}$ represents $\delta(^{60}\text{Ni}/^{58}\text{Ni})$.

by terrestrial contamination. The presence of the radioactive nucleus ^{26}Al in SiC (Groopman et al. 2015) also needs to be analyzed in light of the different grain sizes, together with its production in AGB models of different metallicity. Both the Monash and FRUITY models predict increasing $^{26}\text{Al}/^{27}\text{Al}$ ratios with increasing stellar metallicity (Cristallo et al. 2015; Karakas & Lugaro 2016).

Finally, disentangling possible trends of metallicity versus grain size from observations of elemental abundances in SiC is more difficult than from isotopic ratios because, as mentioned at the start of Section 2, elemental abundances are also affected by the chemistry of dust condensation around AGB stars of different metallicity (see Amari et al. 1995, and Section 5). In any case, available measurements may be in agreement with the metallicity versus size trend proposed here because (i) rare earth elemental abundances measured in bulk KJB grains are in agreement with models of metallicity around solar (Ireland et al. 2018), (ii) larger (KJH) grains contain generally lower elemental abundances than smaller grains (Amari et al. 1995, 2000), and (iii) KJH grains with the highest $\delta(^{29}\text{Si}/^{28}\text{Si})$ ratios also have the lowest abundances of Ce relative to Y (see Figure 3 of Amari et al. 1995).

4. Comparison between AGB Nucleosynthesis Models and Ni and Ti Grain Data

In Figure 3, we present a comparison between SiC grain data from Trappitsch et al. (2018) and AGB model predictions for

the Ni isotopes. We consider AGB models including s -process nucleosynthesis calculated based on the Monash code (Karakas 2014; Karakas & Lugaro 2016). The models presented here are the same models described in detail in Lugaro et al. (2018) and already used by those authors for comparison to Sr, Zr, and Ba in SiC grains. For Fe, we present similar plots as in Figure 4. Single-grain measurements of both Fe and Ni suffer from terrestrial contamination, which may move any data point closer to solar relative to its true composition. For the Ni isotopes, especially in the $\delta(^{61,92,64}\text{Ni}/^{58}\text{Ni})$ three-isotope plots, both the measured and predicted variations are significant. Furthermore, AGB predictions for different masses and metallicities lie on lines with different slopes, which are not sensitive to contamination. In contrast, for Fe, only small variations are observed and predicted for $\delta(^{57}\text{Fe}/^{56}\text{Fe})$, and the measurement uncertainties are too large to clearly distinguish the effects predicted by lines with different slopes, making it more difficult to draw conclusions based on Fe than on Ni.

For Ni, a good match is generally achieved between measurements and models both at solar and twice solar metallicity (Figure 3). In both cases, the most massive models ($3.5\text{--}4 M_{\odot}$) present the best match to the data. As shown in Figure 5 for $Z = 0.03$, the full range of observations can be covered when changing the extent in mass of the mixing of protons that leads to the formation of the ^{13}C pocket, leaving the same profile of the proton abundance (see Buntain et al. 2017, for a detailed description of the difference between extent and

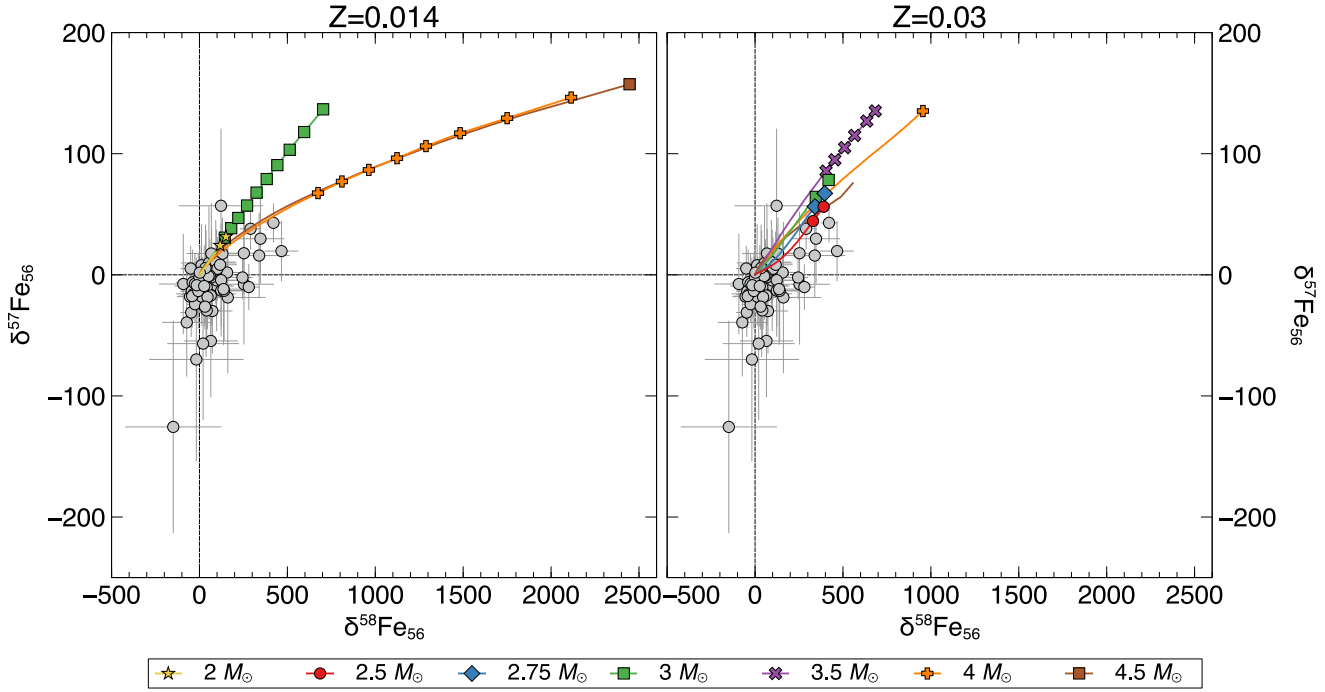

Figure 4. Same as Figure 3 but for selected Fe isotopic ratios.

profile). As in the case of Sr, Zr, and Ba (Lugaro et al. 2018), a somewhat smaller extent in the mass of the mixing provides better coverage of the data. However, the $4 M_{\odot}$, $Z = 0.014$ model should be excluded because it predicts positive $\delta(^{96}\text{Zr}/^{94}\text{Zr})$ instead of negative, as seen in the grains. This is due to the opening of the branching point at ^{95}Zr during the marginal activation of the ^{22}Ne neutron source (Lugaro et al. 2003), where, in our models for the cross section of $^{95}\text{Zr}(n, \gamma)^{96}\text{Zr}$, we use the relatively low value of 28 mbarn at 30 keV presented in Lugaro et al. (2014). The $3.5 M_{\odot}$, $Z = 0.014$ and the 3.5 and $4 M_{\odot}$, $Z = 0.03$ models instead provide a possible match to the measured $\delta(^{96}\text{Zr}/^{94}\text{Zr})$ values within the nuclear uncertainties (see Figure 2 of Lugaro et al. 2018).

Another factor to consider is the uncertainties in the neutron-capture cross sections of the Ni isotopes. For ^{58}Ni , ^{62}Ni , and ^{63}Ni , these were recently measured at the n_TOF facility at CERN (Lederer et al. 2013, 2014; Žugec et al. 2014). In our temperature range of interest, from 5 to 30 keV, the values for ^{58}Ni and ^{62}Ni differ at most by 10% from the values listed in the Kadonis v0.2 database (Dillmann et al. 2006), which we have used in the calculations, while for ^{63}Ni , the neutron-capture cross section is a factor of 2 higher. We tested the impact of these new rates on the models presented in Figure 3 and found variations of less than 10% in the plotted isotopic ratios. For ^{62}Ni , we also tested the changes resulting from the uncertainties in the neutron-capture cross section and found that these changes are at most 12% when varying the cross section by 2σ . Therefore, no significant variations result for the models plotted in Figure 3.

In Figures 6 and 7, we consider the Ti isotopic ratios that are significantly affected by AGB nucleosynthesis: $\delta(^{49}\text{Ti}/^{48}\text{Ti})$ and $\delta(^{50}\text{Ti}/^{48}\text{Ti})$. There is no significant difference in the results when changing the metallicity from solar to twice solar, although the models of higher metallicity and mass—which, as discussed above, generally provide a good match to Ni and Zr—provide a worse fit for $\delta(^{49}\text{Ti}/^{48}\text{Ti})$. The neutron-capture

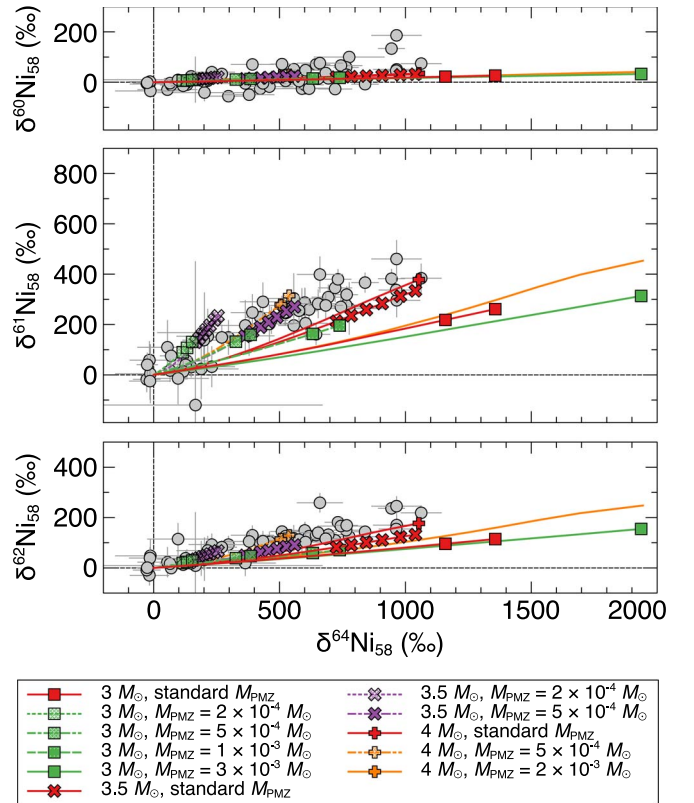

Figure 5. Comparison between single KJG SiC data for the Ni isotopes from Trappitsch et al. (2018) and the AGB model predictions of Lugaro et al. (2018) at twice solar ($Z = 0.03$) metallicity, initial stellar masses between 3 and $4 M_{\odot}$, and different extent of the mass of the mixing of protons required to form the ^{13}C pocket (M_{PMZ}). As in Figure 3, isotopic ratios are plotted on top of the lines only when $\text{C} > \text{O}$ is achieved in the envelope.

cross section of ^{49}Ti was measured in the 1970s and could suffer from strong systematic uncertainties (see the Kadonis database). When we multiplied its value by a factor of 2 in the

Figure 6. Same as Figure 3 but for selected Ti isotopic ratios and data for single grains of size $\gtrsim 2.5 \mu\text{m}$ from Gyngard et al. (2018).

$3.5 M_{\odot}$, $Z = 0.03$ model, we obtained a decrease of 45 in $\delta(^{49}\text{Ti}/^{48}\text{Ti})$, which results in a better agreement with the measurements. We note that both $\delta(^{49}\text{Ti}/^{48}\text{Ti})$ and $\delta(^{50}\text{Ti}/^{48}\text{Ti})$ ratios show a strong and mild, respectively, correlation with $\delta(^{47}\text{Ti}/^{48}\text{Ti})$ (Gyngard et al. 2018), which is not affected at all by nucleosynthesis in AGB stars and is dominated by galactic chemical evolution and heterogeneities in the interstellar medium. These effects must therefore also play a role in all of the Ti isotopic ratios in SiC grains. Furthermore, mass-independent fractionation effects have also been shown to mimic the Ti isotopic anomalies observed in the grains (Robert et al. 2020). Overall, AGB nucleosynthesis models cannot be used alone to compare to the Ti data.

Finally, we note that Palmerini et al. (2018) also successfully matched most of the Sr, Zr, and Ba SiC data by considering a ^{13}C pocket generated by magnetically induced mixing, and Liu et al. (2018a) demonstrated that using a specific parameterization of the ^{13}C pocket, aimed at representing the effect of such magnetically induced mixing, also produces a match to the Ni and Sr data. Here and in Lugaro et al. (2018), we have presented another solution, obtained by keeping a basic exponential mixing profile to generate the ^{13}C pockets but changing the stellar metallicity to $Z = 0.03$. Battino et al. (2019) presented yet another possible solution for the Sr data by including mixing within the ^{13}C pocket.²⁴ This degeneracy of available solutions illustrates that a variety of hypotheses can be made to cover the grain data and demonstrates that it is not possible to constrain the ^{13}C pocket, stellar metallicity, or mixing processes only by comparing the grain data to the stellar models. The comparison to the Ba-star spectroscopic data presented in Section 3 therefore appears to be a more reliable method to investigate the origin of the grains. However, we note that only the AGB models of $3.5\text{--}4 M_{\odot}$ and $Z = 0.03$ can explain the $\delta(^{92}\text{Zr}/^{94}\text{Zr})$ values around and above zero measured in many mainstream SiC grains without affecting the match to any other isotopic ratios (Lugaro et al. 2018).

²⁴ These authors' results do not predict enough of a deficit in ^{96}Zr to match the data; this is related to the activation of the ^{22}Ne neutron source in their models.

5. Dust Formation around AGB Stars of Supersolar Metallicity

Thus far, we have presented evidence that large ($\approx \mu\text{m}$ -sized) mainstream SiC grains originated from AGB stars of metallicity higher than solar. Now the question arises as to why this should be the case, since we may not expect a large number of low-mass stars of such metallicity to have evolved prior to the formation of the Sun. A first consideration is that the simple picture of galactic chemical evolution where metallicity increases with age is well known to be inaccurate, as observations of large stellar samples show that there is no strong correlation between age and metallicity in the Galaxy. These surveys show that stars with ages between that of the Sun and roughly 8 Gyr have a spread in metallicity from 0.3 to 2.5 solar (Mishenina et al. 2013; Bensby et al. 2014; Hayden et al. 2015). This is currently explained by inhomogeneous galactic chemical evolution models, which predict a large spread in metallicity with age (e.g., Kobayashi et al. 2011a) and/or the effect of stellar migration in the Galaxy (e.g., Spitoni et al. 2015).

However, a second consideration is that the metallicity required for the parent stars of the large SiC grains is roughly twice as high as the average metallicity of stars in the solar neighborhood. As proposed already by Lewis et al. (2013) in relation to Si, the shift to higher metallicity in the distribution of the parent stars of the SiC grains relative to lower-mass, unevolved stars in the solar neighborhood (of the same age as the higher-mass evolved parent stars of the SiC grains) may be related to a selection effect arising from the process of dust formation in AGB stars. In this section, we analyze this possibility in more detail.

We consider AGB stellar models calculated with the ATON code (Ventura et al. 2012), which include the process of dust formation. For a comparison between the ATON models and the Monash models used in the previous section to discuss the s -process results, see Ventura et al. (2018). In general, depending on whether the gas is O-rich (such as in the presolar nebula and disk) or C-rich (as in some AGB stars), fundamentally different minerals can form (Lodders & Fegley 1997; Lodders 2003). Here we are focusing on

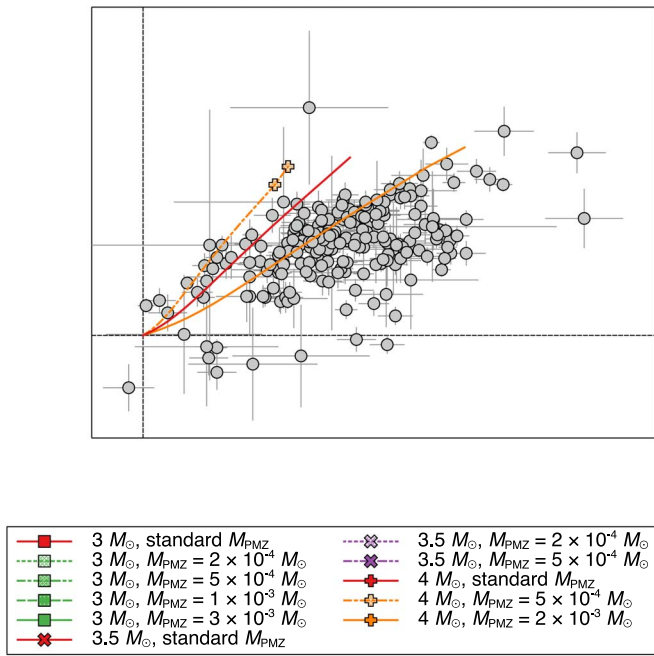

Figure 7. Same as Figure 5 but for selected Ti isotopic ratios and data from Figure 6.

supersolar metallicity models that reach $C/O > 1$, since we are interested in the formation of SiC grains at such metallicities. Other models of dust formation around AGB stars can be found, e.g., in Nanni et al. (2013, 2014); however, the AGB stars of supersolar metallicity ($Z = 0.04$) presented in those papers are not C-rich. The reaching of the $C/O > 1$ condition is strongly dependent on the treatment of mixing along the AGB and how it affects the efficiency of the TDU that carries C to the surface when changing the stellar metallicity. The ATON models and the Monash models discussed in Section 4 at $Z = 0.03$ both become C-rich for masses from roughly 2.5 to 4 M_{\odot} .

Physical conditions for dust formation around AGB stars involve nonequilibrium effects with regard to both chemistry and thermodynamics (including pulsations, stellar winds, and possible shocks; see, e.g., Sedlmayr & Krüger 1997; Höfner & Olofsson 2018). The model adopted in ATON for the dust formation in AGB circumstellar envelopes was presented for the first time by Gail & Sedlmayr (1985, 1999) and Ferrarotti & Gail (2001, 2002, 2006). In brief, the growth of dust particles is calculated on the basis of the gas density and thermal velocity at the inner border of the condensation region during the evolution of the AGB star based on the luminosity, mass, effective temperature, mass-loss rate, and surface chemical composition. Dust grain formation is determined by growth and destruction rates. The first is defined by the deposition efficiency of gaseous molecules on solid seed particles (of nominal size of 1 nm) assumed here to be already formed by a prior nucleation process. For each dust species, the decomposition rate is calculated via the evaluation of the vapor pressures of the individual molecular species involved under thermodynamic equilibrium conditions (Gail & Sedlmayr 1999).

In Figure 8, we show the predicted amounts of dust ejected by AGB stars of different stellar mass and metallicity for different types of dust. In general, the mechanism for grain growth stops when the density decreases such that gas molecules cannot interact and accrete on the existing dust

anymore. However, in the case of SiC, only 55% of the Si is available to accrete onto existing SiC dust grains because the other 45% is already locked into the SiS molecules, which are very stable. Figure 8 shows that for C-rich AGB stars of metallicities higher than solar, the amount of SiC ejected is greater than or comparable to that of carbon dust. This is in contrast to the case of stars of lower metallicity, where solid carbon is instead the dominant type of dust. For example, considering the 2.5 M_{\odot} models, at $Z = 0.03$, SiC is more than 1 order of magnitude greater than solid carbon, while it is six times lower in the case of $Z = 0.014$. The amount of carbon dust depends on the number of carbon atoms available for condensation after the formation of the extremely stable CO molecules, i.e., the carbon excess with respect to oxygen. The growth of SiC particles is instead determined by the silicon abundance. At higher metallicity, the C/O ratio is lower, because for the same amount of C dredged up to the surface, there is more initial O in the envelope to overcome. In these conditions, the carbon excess is smaller and SiC condensation is favored with respect to solid carbon, as more silicon is available with respect to the lower-metallicity case. As shown in Figure 8 for the C-rich AGB stars, SiC is the dominant species only if $Z = 0.03$ for the models of 2.5 and 3.5 M_{\odot} . For the 3.0 M_{\odot} model, the amount of SiC is comparable to that of solid carbon. Relative to the $Z = 0.014$ models, the 2.5 M_{\odot} case produces the same amount of SiC, while the 3 M_{\odot} model produces three times less. (The 3.5 M_{\odot} model remains O-rich and does not produce significant C-rich dust.) This is in disagreement with the distribution shown in the bottom panel of Figure 1, which indicates that AGB stars at $Z = 0.03$ should produce (at least $\sim 50\%$) more SiC relative to the case at $Z = 0.014$.

It should be noted, however, that dust formation models in general carry some uncertainties, particularly related to the mass loss. In the model discussed here, the dust formation rate increases with the mass-loss rate because the mass loss affects the density of the wind (via mass conservation) and thus the number of gaseous molecules available to condense into dust. Carbon stars lose mass at higher rates than O-rich AGB stars because once the surface carbon exceeds oxygen, the surface molecular opacities become extremely large (see, e.g., Ventura & Marigo 2010). These opacities favor the expansion of the external regions, which become less and less gravitationally bound to the central star, thus increasing the rate of mass loss and, consequently, dust production. The increase in the molecular opacities does not depend linearly on the C/O ratio, and even a small difference (with 3 M_{\odot} typical values, from 1.1 in the $Z = 0.03$ model to 1.25 in the $Z = 0.014$ model) is sufficient to provoke a significant difference in the rate of mass loss experienced and, in turn, of the total dust production: the 3 M_{\odot} $Z = 0.03$ and 0.014 models, for example, produce a total dust mass of 2.82×10^{-3} and $1.35 \times 10^{-2} M_{\odot}$, respectively, a factor of 5 difference. To illustrate the significant effects of these uncertainties, we consider for comparison the models presented by Ferrarotti & Gail (2006), which are not based on the use of C/O-dependent molecular opacities. In this case, the most relevant quantity for the formation of SiC is the silicon abundance. Predictions from these models are therefore different from those presented here; for example, the 3 M_{\odot} , $Z = 0.04$ models of Ferrarotti & Gail (2006) produce four times more carbon dust than SiC and, relative to $Z = 0.02$, a similar amount of total dust and four times more SiC.

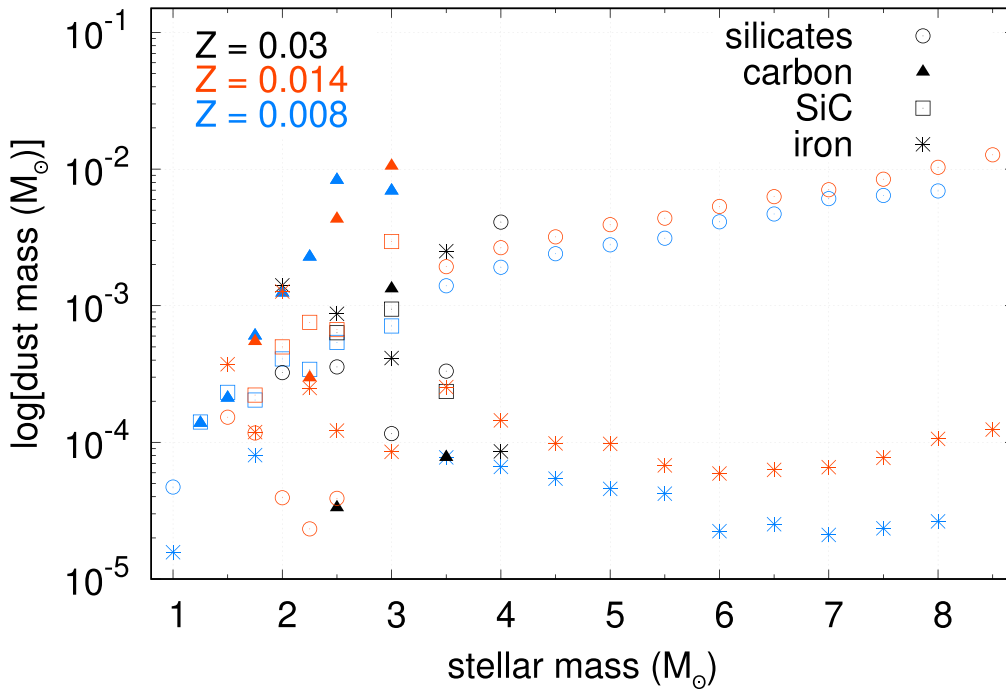

Figure 8. Amount as a function of the initial stellar mass of different types of dust (silicates, carbon, SiC, and iron; different symbols) in AGB stars of metallicities from roughly half to twice solar (different colors) predicted by the ATON models. Carbon and SiC dust is produced in C-rich AGB stars in the mass range from roughly 2 to $3.5 M_{\odot}$.

The other crucial feature, discussed in Section 2.2 is the size of the dust grains. In the ATON models, all SiC grains reach a maximum diameter of $0.26 \mu\text{m}$, with an approximate lower limit of $0.16 \mu\text{m}$. It is not possible to form larger grains because all of the gaseous silicon is already either locked into SiS molecules or condensed into SiC grains. These maximum dimensions correspond to grains within the meteoritic KJA fraction and exclude the large grains belonging to the KJE and KJG fractions that we are considering here to originate in stars of supersolar metallicity. While we found that the velocity with which the gas enters the condensation region does not significantly influence the grain size, the density of the seed dust grains, assumed in the model to be already present in the AGB envelope and to act as seeds onto which larger dust can grow, has a strong impact. Because the amount of Si available to condense into SiC is fixed, if there are fewer seeds, the final SiC grain size is larger. In the models presented above, we used a value for the number of seed dust grains of $N_d = 10^{-13} N_H$, where N_H is the number of H atoms. This number reflects, as an order of magnitude, the average estimate based on the analysis of a sample of Galactic giants presented by Knapp (1985) and is commonly assumed in the models to be independent of the dust species and stellar metallicity, which is not necessarily correct. If we decrease N_d by a factor of 100 or 1000, the grains reach a size of 1.2 and $4 \mu\text{m}$, respectively, which would cover the meteoritic SiC of fractions KJD–KJE and KJG, respectively (Table 1). Therefore, if the number of seeds decreases with increasing metallicity, this would result in a selection effect where the larger SiC grains preferentially form in stars of higher metallicity.

6. Summary, Discussion, and Conclusions

We have presented a new approach to identifying the origin of meteoritic stardust mainstream SiC grains from C-rich AGB

stars based mostly on spectroscopic observations of *s*-process-enriched Ba stars. This approach allows us to reach more robust conclusions because models of nucleosynthesis in AGB stars are prone to many uncertainties, which are bypassed with our new method. For Ba stars, we selected $[\text{Ce}/\text{Y}]$ as the representative signature of the *s*-process nucleosynthesis experienced by their binary AGB companions. For the SiC grains, we selected $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ as the representative signature, since it involves the isotopic ratio affected by the number of neutrons captured per Fe seed that shows the largest range of variations in the grain data.

Our main results are as follows.

1. Due to the existence of nuclei with a magic number of neutrons on the *s*-process path, the *s* process necessarily produces negative $[\text{Ce}/\text{Y}]$ ratios when $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ is also negative. The Ba stars (and *s*-process AGB stellar models) show a clear trend of $[\text{Ce}/\text{Y}]$ decreasing as the metallicity increases (Cseh et al. 2018), and it is statistically more likely for Ba stars of metallicity higher than solar to show negative $[\text{Ce}/\text{Y}]$ ratios (Figure 1). The SiC grains show a range of $\delta(^{88}\text{Sr}/^{86}\text{Sr})$ decreasing with increasing the grain size and down to negative for grains of size $\gtrsim \mu\text{m}$. Therefore, the larger grains should have originated from AGB stars of higher metallicity than the smaller grains.
2. The isotopic compositions of Ni, Sr, Zr, and Ba in μm -sized grains are well matched by AGB models of metallicity higher than solar (see also Lugaro et al. 2018). The composition of Si is mostly affected by the chemical evolution of the Galaxy and also points to the grains coming from stars of metallicity higher than solar (see also Lewis et al. 2013), in particular as their size increases (Amari et al. 2000). For Ti, galactic chemical evolution, as well as mass-dependent fractionation effects

(Robert et al. 2020), will need to be considered together with AGB models.

3. In AGB stellar models of metallicity higher than solar, SiC is typically the dominant type of dust produced; however, these models produce lower absolute masses of SiC, and dust in general, than the models of solar metallicity. In general, the AGB models of dust formation do not predict the grain sizes that are observed for the large SiC grains, unless the number of dust seeds is decreased from 10^{-13} to $10^{-15,-16}$ of the number of H atoms.

Since the most likely sites of the origin of large (μm -sized) mainstream SiC stardust grains are AGB stars of metallicity higher than solar (1), and, in order to produce grains of such size, we need to decrease the number of dust seeds (3), we conclude with the hypothesis that the number of dust seeds in AGB stars should decrease when increasing the metallicity, and that larger SiC dust grains should be present in AGB stars of metallicity higher than solar. Testing this hypothesis with observations of AGB stars using the Atacama Large Millimeter/submillimeter Array or the mid-infrared MATISSE may be possible by observing nearby AGB stars; however, this is not trivial. First, it is difficult to establish the metallicity of AGB stars. One way to indirectly sample variations with metallicity would be to investigate objects at different distances from the galactic center, given that a metallicity gradient exists with the galactic longitude. For example, Groenewegen et al. (2002) found a decrease of the expansion velocity with galactic distance in a sample of 330 infrared carbon stars, possibly due to a higher gas-to-dust ratio outside the solar circle than inside and related to the metallicity gradient. Second, it is difficult to firmly establish grain sizes from observations because not only the size but also the radiative transfer effects due to the detailed density stratification of dust and the opacity profile of SiC may change the shape of the SiC spectral feature. Finally, it is difficult to disentangle the properties of SiC from those of amorphous carbon dust. Using interferometric imaging, it may be possible to see a change in the wavelength-dependent appearance if SiC really is located further in than carbon (as observed, for example, for the dust mineralogy around young stellar objects; van Boekel et al. 2006). The number of SiC seeds could also be derived by comparing the depletion of molecular SiC between targets of similar mass loss. However, SiC molecular features are not obvious, and in general, their observation involves a large number of uncertainties. Grain sizes can be estimated from polarimetry (combined with interferometry), as shown for O-rich grains (Norris et al. 2012). However, this also involves a large number of parameters and uncertainties. In parallel, more work is needed from the theoretical point of view using different dust formation models for supersolar metallicities (e.g., extending the models of Bladh et al. 2019), and the consequences for the mass loss and spectral energy distribution of larger and more abundant SiC grains in stars of higher metallicity need to be considered.

One important point to keep in mind is the definition of metallicity in relation to all the different aspects we are considering here and the solar metallicity. On the one hand, for Ba stars, metallicity refers to $[\text{Fe}/\text{H}]$, and since the abundance of Fe is relatively well established in the solar system, we can confidently conclude that Ba stars with an Fe abundance of twice the solar abundance show predominantly negative

$[\text{Ce}/\text{Y}]$. On the other hand, when we consider stellar models, C and O are the main elements contributing to the metallicity. The abundances of these elements strongly affect the opacity, both deep in the star, where the *s* process occurs, and in the envelope, where the dust forms. Furthermore, since the lower solar O abundance determined via spectroscopy is still in disagreement with helioseismology data (e.g., Vinyoles et al. 2017), the overall solar metallicity is still uncertain. Thus, whether the $Z = 0.03$ AGB models represent stars of twice solar metallicity based on the lower O abundance from Asplund et al. (2009; giving $Z = 0.014$) or 1.5 times solar based on the O abundance from the older compilation by Anders & Grevesse (1989; $Z = 0.02$) is uncertain. As a result, we do not consider it a strong inconsistency that the $[\text{Ce}/\text{Y}]$ ratios in Ba stars indicate that most large grains should come from stars with Fe twice solar, while Lewis et al. (2013), based on models of the galactic chemical evolution of Si, derived that the majority of SiC grains should have formed in AGB stars of metallicity from solar to 70% above solar. We note that Lewis et al. (2013) did not make any distinction among grains of different sizes, while this point should be considered in the future. Similar studies should also be performed in relation to silicate grains that originated from O-rich AGB stars and show a similar Si isotopic distribution as SiC (Hoppe et al. 2018), although no *s*-process isotopic ratios are available for such grains. More detailed studies are also needed to verify the compatibility of our results with the composition of the noble gases and other elements, such as Mo, W, Hf, and Pb.

Based on the fact that bulk meteorite analyses show smaller-magnitude *s*-process variations in the heavier (second-peak) relative to the lighter (first-peak) refractory *s*-process elements, Ek et al. (2020) suggested that high-metallicity AGB stars may have been a dominant source of stardust in the early solar system. This suggestion was based on the fact that AGB stars of higher metallicity produce fewer second-peak *s*-process elements relative to the first peak (see Section 2.1). If this idea is correct, our results further indicate that the large SiC grains represent the material from high-metallicity AGB stars that is needed to interpret the bulk rock anomalies. In this case, these large grains should represent a significant fraction of presolar stardust in the solar system. Large grains obviously carry more material than small grains, but their impact will also depend on numbers. By number, the grains of different sizes appear to follow a power-law distribution above $\sim 0.6 \mu\text{m}$ (see Figure 8 of Amari et al. 1994), although this result is not conclusive because many smaller grains could have been lost because of the chemistry used to make the K-series residues. A more detailed analysis is required. Theoretically, if large SiC grains survive longer in the interstellar medium than small SiC grains, they may have been preferentially present in the presolar cloud. More detailed laboratory and theoretical investigations on this topic are required. Although challenging, more data on Sr and Ba isotopes in different solar system materials will advance our understanding of the presence and evolution of presolar dust and stardust in the solar protoplanetary disk.
