ABSTRACT

The XQ-100 survey has provided high signal-noise spectra of 100 redshift 3–4.5 quasars with the X-Shooter spectrograph. The metal abundances for 13 elements in the 41 damped Ly α systems (DLAs) identified in the XQ-100 sample are presented, and an investigation into abundances of a variety of DLA classes is conducted. The XQ-100 DLA sample contains five DLAs within 5000 km s^{−1} of their host quasar (proximate DLAs; PDLAs) as well as three sightlines which contain two DLAs within 10 000 km s^{−1} of each other along the same line of sight (multiple DLAs; MDLAs). Combined with previous observations in the literature, we demonstrate that PDLAs with log $N(\text{H I}) < 21.0$ show lower [S/H] and [Fe/H] [relative to intervening systems with similar redshift and $N(\text{H I})$], whilst higher [S/H] and [Si/H] are seen in PDLAs with log $N(\text{H I}) > 21.0$. These abundance discrepancies are independent of their line-of-sight velocity separation from the host quasar, and the velocity width of the metal lines (v_{90}). Contrary to previous studies, MDLAs show no difference in $[\alpha/\text{Fe}]$ relative to single DLAs matched in metallicity and redshift. In addition, we present follow-up UVES data of J0034+1639, a sightline containing three DLAs, including a metal-poor DLA with [Fe/H] = −2.82 (the third lowest [Fe/H] in DLAs identified to date) at $z_{\text{abs}} = 4.25$. Lastly we study the dust-corrected [Zn/Fe], emphasizing that near-IR coverage of X-Shooter provides unprecedented access to Mg II, Ca II and Ti II lines (at redshifts 3–4) to provide additional evidence for subsolar [Zn/Fe] ratio in DLAs.

Key words: galaxies: abundances – galaxies: high redshift – galaxies: ISM – quasars: absorption lines.

1 INTRODUCTION

Quasars (QSOs) exist at many different epochs, providing lines of sight through pockets of gas from the epoch of reionization

to the present day. One of the classes of intervening absorbers towards QSOs are damped Ly α systems (DLAs; Wolfe, Gawiser & Prochaska 2005), defined by their large H I column densities [$N(\text{H I}) \geq 2 \times 10^{20}$ atoms cm^{−2}; Wolfe et al. 1986]. DLAs are common probes to study the evolution of neutral gas and metals in the interstellar medium (ISM) of galaxies from $z_{\text{abs}} \sim 5$ to the present day (Wolfe et al. 1995; Pettini et al. 1997; Prochaska &

*E-mail: trystynb@uvic.ca.

Herbert-Fort 2004; Rao, Turnshek & Nestor 2006; Rafelski et al. 2014; Sánchez-Ramírez et al. 2016).

A large portion of DLA analyses has been concentrated on detailed abundance analyses of the host galaxies (e.g. Pettini et al. 1994; Lu, Sargent & Barlow 1998; Centurión et al. 2000; Wolfe, Prochaska & Gawiser 2003; Cooke et al. 2011; Zafar et al. 2014a; Berg et al. 2015b). As elements have unique physical properties and nucleosynthetic origins (Woosley & Weaver 1995; McWilliam 1997; Nomoto, Kobayashi & Tominaga 2013), different abundance ratios have been used to understand the star formation history and dust content of DLAs (Ledoux, Bergeron & Petitjean 2002; Prochaska & Wolfe 2002; Vladilo et al. 2011). The most common ratio to probe enrichment histories is $[\alpha/\text{Fe}]$, which traces the star formation history due to the time-delayed contributions of Type II and Ia supernovae (Tinsley 1979; McWilliam 1997; Venn et al. 2004; Tolstoy, Hill & Tosi 2009). However elements such as Fe, Ni, and Cr are heavily depleted onto dust (Savage & Sembach 1996), leading to overestimates of the measured gas-phase $[\alpha/\text{Fe}]$ in DLAs. These overestimates in $[\alpha/\text{Fe}]$ have led to the use of other undepleted elements that trace Fe (such as Zn) to better estimate the intrinsic $[\alpha/\text{Fe}]$ ratio (Pettini et al. 1997; Vladilo 2002a). In the case of Zn, care must be taken as Zn does not necessarily trace Fe in all environments and metallicities (Prochaska et al. 2000; Chen, Nissen & Zhao 2004; Nissen et al. 2007; Rafelski et al. 2012; Berg et al. 2015b).

The physical nature of DLAs also influences their gas phase abundances, including the role of ionizing sources (D’Odorico 2007; Ellison et al. 2010; Zafar et al. 2014b) or the amount of dust (e.g. Pettini et al. 1994; Kulkarni, Fall & Truran 1997; Akerman et al. 2005; Krogager et al. 2016). There are many subclasses of DLAs that provide opportunities to probe these differing physical environments. Proximate DLAs (PDLAs) are DLAs defined to be within $\Delta v \leq 5000 \text{ km s}^{-1}$ of the host QSO, and more frequently seen than intervening systems (Ellison et al. 2002; Russell, Ellison & Benn 2006; Prochaska, Hennawi & Herbert-Fort 2008b). PDLAs have shown increasing metal abundances with increasing $N(\text{H I})$, in particular both $[\text{S}/\text{H}]$ and $[\text{Si}/\text{H}]$ are $\sim 3 \times$ larger in four PDLAs with $\log N(\text{H I}) > 21.0$ (Ellison et al. 2010; Ellison, Prochaska & Mendel 2011). Multiple DLAs (MDLAs) along the same line of sight within $500 \leq \Delta v \leq 10\,000 \text{ km s}^{-1}$ of each other have also shown different metallicity effects, with a low $[\alpha/\text{Fe}]$ relative to the typical DLA (Ellison & Lopez 2001; Lopez & Ellison 2003); an effect attributed to truncated star formation from environmental effects. However, the analyses of Lopez & Ellison (2003) and Ellison et al. (2010) suffer from low numbers of MDLAs (seven absorbers) and PDLAs (16 absorbers).

Recently there has been a significant effort to identify the first stars and galaxies (Cayrel et al. 2004; Beers & Christlieb 2005; Suda et al. 2008; Spite et al. 2011; Frebel & Bromm 2012; Norris et al. 2013; Frebel & Norris 2015) to constrain Population III nucleosynthesis (Umeda & Nomoto 2002; Greif et al. 2007; Heger & Woosley 2010; Cooke et al. 2013). In tandem with the search for metal-poor stars in the Galaxy and its nearby companions (e.g. Jacobson et al. 2015; Skúladóttir et al. 2015), work at higher redshifts focused the identification and measurement of abundances in the most metal-poor DLAs (MPDLAs; $[\text{Fe}/\text{H}] \leq -2.5$; Penprase et al. 2010; Cooke et al. 2011; Becker et al. 2012; Cooke & Madau 2014). As the explosion mechanism of the supernovae models is very uncertain, chemical abundances in these metal-poor regimes are required to constrain the models of Population III nucleosynthesis. In particular, the supernovae explosion energy influences the mass cut of the supernovae, and thus which elements escape into

the ISM (Umeda & Nomoto 2002; Nomoto et al. 2013). To date, abundances in the most MPDLAs reflect first-generation stars that have undergone moderate to low-energy core-collapse supernovae (Cooke et al. 2011, 2013), but remains to be tested for a large sample of DLAs with $[\text{Fe}/\text{H}] \leq -3$.

The XQ-100 Large Programme survey (PI: S. Lopez, ESO ID 189.A-0424; López et al. 2016) has observed 100 QSOs at $z = 3.5\text{--}4.5$ with the X-Shooter (Vernet et al. 2011) spectrograph on the Very Large Telescope (VLT). As the survey was primarily designed to study active galactic nuclei, the intergalactic medium, and the Ly α forest, XQ-100 provides a near-random sample of intervening DLAs as the QSOs were selected without consideration of intervening absorbers. In this paper, we present the metal column densities for 14 species (O I, C II, Mg I, Mg II, Ca II, Si II, P II, S II, Ti II, Cr II, Mn II, Fe II, Ni II, Zn II) in the DLAs recently identified by Sánchez-Ramírez et al. (2016) in the XQ-100 survey. By combining the XQ-100 DLAs with a sample of DLA abundances in the literature (Berg et al. 2015b), we investigate the elemental abundances of the XQ-100 sample and demonstrate the prospects of using X-Shooter to study absorption lines in the near-infrared (NIR).

2 DATA

In this section, we present the DLA abundances derived in this work. The spectra used come from the XQ-100 survey (López et al. 2016), as well as follow-up observations with VLT/UVES for one sightline (J0034+1639).

2.1 XQ-100 abundances

The XQ-100 data set consists of 100 QSOs observed with X-Shooter towards QSO sightlines at redshift $z_{\text{em}} \sim 3.5\text{--}4.5$. The per-arm exposures were either ~ 0.5 or ~ 1 h in length (depending whether the QSO was classified as ‘bright’ or ‘faint’; respectively), providing signal-noise ratios (snr) of $\sim 20 \text{ pixel}^{-1}$ (median $\sim 30 \text{ pixel}^{-1}$) at resolution $R \sim 5000\text{--}9000$ from the near UV ($3150 \text{ \AA}$) to the NIR ($25\,000 \text{ \AA}$). The spectra were reduced using an internal IDL package. For more details, see López et al. (2016).

The DLAs were identified and H I column densities determined in Sánchez-Ramírez et al. (2016). Table 1 summarizes the DLAs identified in the XQ-100 survey, along with their redshifts,¹ $\log N(\text{H I})$ and line-of-sight velocity separations from the QSO (Δv). In Sánchez-Ramírez et al. (2016), the H I column densities were determined by simultaneously fitting the Lyman series (up to Ly ϵ). Redshifts were primarily determined from the H I fits, but in some cases were guided by the metal lines.

The XQ-100 spectra are released with two options for continuum fits. One option uses a power law with select emission lines incorporated to fit each spectrum, providing complete wavelength coverage. However, this power-law continuum does not provide a good fit around missing QSO emission lines, and therefore cannot be used for accurate DLA abundances in some cases. In this paper, we use the alternative option, a by-hand fit to the continuum using a cubic spline,² similar to the approach of Sánchez-Ramírez et al. (2016). The error spectra were normalized by the same continuum fit.

¹ For J0034+1639, the redshifts of the DLAs have been tweaked based on the metal lines in the UVES spectra presented in Section 2.2.

^P – Proximate DLA^M – Multiple DLA

Metal column densities

Column densities were derived using the Apparent Optical Depth Method (AODM) presented in Savage & Sembach (1991). In brief, this method sums the optical depth of an unsaturated absorption feature (at wavelength λ with oscillator strength f ; taken from Morton 2003), converting the total optical depth into a column density using

$$N = \frac{m_e c}{\pi e^2 f \lambda} \int_{v_{\min}}^{v_{\max}} \tau dv. \quad (1)$$

The integration limits $v_{\min}$ and $v_{\max}$ are selected such that the associated metal absorption profile are bounded by these velocity limits. We attempted to use the same velocity limits for all metal lines for a given DLA, however the velocity limits were sometimes adjusted on a line-by-line basis to exclude regions of contamination outside the metal absorption feature. If the weaker components of a shallow line are undetected, the velocity limits

are purposefully made narrow to only contain associated absorption, and exclude flux contribution from the continuum. When the column density is derived using multiple clean lines for the same ion, we adopt the average value ($\log N_{\text{adopt}}$) and the standard error (with a minimum error of 0.05 dex). For features that exhibited obvious blending or saturation, we measure the AODM column density as a limit to the true value, adopting the most constraining limit as the final value. For cases where the absorption feature is severely blended, we do not consider adopting the measured column density.

The limiting spectral resolution of X-Shooter ($R=5100$, 8800, and 5300 for the UV, visible, and NIR arms; respectively) implies that there are cases where we cannot determine the presence of unseen contamination or saturation visually. Cases of hidden contamination or saturation were flagged when multiple lines are measured for a given species and resulted in significantly inconsistent column densities. Using multiple Si II and Fe II lines, we have noted that these cases of hidden saturation tend to occur when the strongest absorption reaches a relative flux of ~ 0.3 – 0.5 (similar to the ~ 0.25 seen in the UVB arm by Krogager et al. 2016). Lines with absorption stronger than ~ 0.5 (in units of relative flux) were inspected for inconsistent column densities with other lines. Unless the derived column density is consistent with weaker lines, any discrepant column densities were flagged as saturated. We note that all of the lines with a peak absorption at ~ 0.5 had additional lines to constrain potential saturation. However, there may still be cases with unresolved saturation or blending unaccounted for.

When weak lines are not detected and the spectrum is uncontaminated, we measure 3σ upper limits based on the ability to detect the strongest absorption feature within the snr of the spectrum using

$$N = \frac{3m_e c \text{FWHM}}{\pi e^2 f \lambda^2 (1 + z_{\text{abs}}) \text{snr}}, \quad (2)$$

where FWHM is the full width at half-maximum of the strongest absorption feature. As the components of the absorption profile are likely limited by the resolution of the instrument ($\Delta v \sim 55$ km s $^{-1}$) rather than the DLA kinematics ($\Delta v \sim 10$ km s $^{-1}$; e.g. Dessauges-Zavadsky et al. 2004; Jorgenson, Wolfe & Prochaska 2010; Tumlinson et al. 2010; Cooke & Madau 2014), we assume that the FWHM of this strongest absorption feature to be equal to the resolution limit of X-Shooter in the setup with a slit width of ~ 1 arcsec. The snr for the 3σ upper limits was computed within the bounds of the AODM limits.

As an example of data quality and coverage, Fig. 1 shows the velocity profile for all the observed lines of the DLA in the spectrum of J0003–2603 ($z_{\text{abs}} = 3.39$). The vertical dashed lines show the velocity limits used to integrate the spectrum for the AODM column density determinations. The column densities for all the measured lines for the DLA towards J0003–2603 are given in Table 2. Table 2 displays the wavelength and oscillator strength of the absorption line (Morton 2003), the velocity integration bounds of the absorption feature used ($v_{\min}$ and $v_{\max}$), the measured column density $\log N(X)$ of the metal line, and whether the derived column density was included for the final computation of the adopted column density ($\log N_{\text{adopt}}$). The adopted $\log N_{\text{adopt}}$ is given for each species in the last row for the species. Appendix A1 (see Supporting Information) contains the velocity profiles (Figs A1–A21) and abundances (Tables A1–A21) for the remaining DLAs. If the adopted column density for a given species is best constrained by an upper and lower limit, the range of possible values is provided in

Figure 1. Velocity profile of the XQ-100 spectrum towards J0003–2603 ($z_{\text{abs}}=3.390$). The vertical dashed lines indicated the AODM velocity bounds. Regions of the spectrum that are contaminated by strong, unassociated absorption are flagged as dotted lines.

Tables A1–A21. A summary of the final adopted column densities for all DLAs is listed in Table 3.³

v_{90} parameter

Following the analysis techniques described in Prochaska & Wolfe (1997), we have assessed the kinematic characteristics of the XQ-100 DLA sample. In particular, we have measured the velocity width v_{90} corresponding to 90 per cent of the integrated optical depth using one low-ion transition per DLA (listed in Table 4). We selected transitions according to the spectral S/N, avoiding saturated or weak absorption profiles. The optical depth per pixel was calculated from the normalized flux values and then smoothed by a boxcar with width of 22 km s^{-1} as in Prochaska & Wolfe (1997).

From these smoothed optical depth arrays, we calculate the velocity width comprising 90 per cent of the integrated optical depth between the AODM integration bounds.

Adopting the results of Prochaska et al. (2008a) who also analysed a set of echellette observations ($R \approx 8000$), we have reduced the raw v_{90} values to correct for instrumental broadening. Specifically, we lower the raw v_{90} measurements by 30, 17, and 25 km s^{-1} for the UVB, VIS, and NIR arms, respectively. These corrections correspond to ≈ 40 per cent of the FWHM of the instrumental line-spread-function for our X-Shooter configuration. The final, reported v_{90} values are presented in Table 4.

Comparison to literature measurements

Of the DLAs studied in XQ-100, 15 DLAs have previously been observed in the literature sample of Berg et al. (2015b, further referred to as the literature sample). The literature sample includes abundance determinations for a variety of

³ The adopted column densities in Table 3 for the DLAs towards J0034+1639 are preferentially adopted from the UVES data presented in Section 2.2.

elements⁴ using high-resolution spectrographs (predominantly VLT/UVES, Keck/HIRES, and Keck/ESI) for 341 DLAs between $z_{\text{abs}} \sim 0$ and 5.

Similar to the comparison of $N(\text{H I})$ to the literature in Sánchez-Ramírez et al. (2016), Table 5 compares the metal column densities for the 15 DLAs common between the literature and XQ-100. $\Delta N(\text{X})$ represents the difference in column density between the value determined in this work and the value in the literature sample (where a positive difference implies the XQ-100 column density is larger than what is in the literature). When both the literature and XQ-100 measurements yield a clean detection, we compare difference in column densities ($\Delta N(\text{X})_{\text{det.}}$) to the combined column density errors. Consistent values of $\Delta N(\text{X})_{\text{det.}}$ should be of the order of the combined error, although the quoted errors in metal column densities do not generally account for sources of error other than photon noise (e.g. continuum fitting) and can be larger. For most of the detections, we see consistent values between XQ-100 and the high-resolution literature (to within 0.05 dex). The discrepant cases (the bolded ionic species in Table 5) are discussed in Appendix B (see Supporting Information). In all cases, the column densities derived in this work are adopted as they are consistent with

the literature values (see Appendix B for justification of discrepant cases).

For cases where both the XQ-100 and literature measurements are upper limits ($\Delta N(\text{X})_{\text{lim.}}$; positive values indicate that the XQ-100 limit is higher than the literature), 4 of 10 XQ-100 upper limits are more constraining than the literature column density derived from Keck/ESI data with comparable resolution. Naturally, the higher resolution instruments provide more constraining upper limits due to their ability to resolve narrower features within the fluctuations of the continuum. For all cases where the literature provides better limits (or detections, as in the case for Ni II and Zn II in J2344+0342 at $z_{\text{abs}} = 3.22$), we adopt the literature values.

Continuum-fitting errors

As a baseline for comparison, the spline continuum fitting was done two times to assess the random errors of the continuum fit. The median difference in column density for all lines in the two iterations is 0.0 dex, with an interquartile range of 0.02 dex and 67 per cent of column densities being within ± 0.01 dex. Although the 3σ upper limits are not included in this calculation, it is worth noting that derived column densities for these limits are sensitive to the continuum placement.

⁴ The elements are: N, O, Mg, Al, Si, S, Ca, Ti, Cr, Mn, Fe, Co, Ni, and Zn.

2.2 UVES data for J0034+1639

The X-Shooter spectrum of the $z_{\text{abs}} = 4.25$ DLA (Fig. A4) towards J0034+1639 suggests a very low metallicity system ($[\text{Fe}/\text{H}] = -2.82 \pm 0.11$, third lowest $[\text{Fe}/\text{H}]$ to date; Cooke, Pettini & Jorgenson 2015, see Table A5). The sightline also contains two other DLAs, as well as a number of other H I absorbers (which will be discussed in a future paper).

To confirm the column densities of this metal-poor DLA are free of undetected contamination and saturation, as well as attempting to measure Fe-peak elements such as Ni II to pin-point the underlying supernovae population (Cooke et al. 2013), we obtained VLT/UVES (Dekker et al. 2000) data towards the sightline J0034+1639. The observing Programme (PI: T. Berg; Programme number 094.A-0223A) was organized in five observing blocks (OBs) of 48 min each for a total of 4 h of on-target integration to obtain a signal-noise of 20–25 pixel $^{-1}$. We used the dichroic DIC-2 at the standard setting of 437+760 to obtain wavelength coverage between 6000 and 9000 Å (slit width 0.8 arcsec; $R \sim 80\,000$). The data were reduced

using the standard UVES data-reduction software in REFLEX.⁵ After correcting for the heliocentric velocity, the five OBs were median combined with IRAF’s SCOMBINE, whilst the error spectra were combined in quadrature. The combined spectrum was then continuum normalized using the cubic spline software presented in Section 2.1.

Metal column densities for the three DLAs along the sightline (see Table 1) were derived using the AODM, as in Section 2.1. As UVES can resolve down to the kinematic structure of the DLA clouds, we use the measured FWHM of the strongest component of an unsaturated metal line profile as the minimum equivalent width observable. This FWHM is used in equation (2) to determine the 3σ limits in the absorber. The snr for the 3σ upper limits was computed within the bounds of the AODM limits. Fig. 2 and Table 6 present the velocity profiles of the absorption lines towards the MPDLA and the corresponding column densities. The data for the other absorbers are presented in the same format in Appendix A2 (see Supporting Information).

In general, we preferentially adopt the UVES column density as the higher resolution provides an accurate determination of the absorption profile and the data has a similar or higher snr . The one exception where we adopt the XQ-100 value is due to a lack of strong, uncontaminated Fe II lines covered in the UVES spectrum required to derive an accurate column density. We note that the absorption in the Ni II 1741 Å panel of Fig. 2 is likely contaminated as it does not produce a consistent measurement with the derived column density limits for the Ni II 1709 and 1751 Å lines.

2.3 XQ-100 sample properties

To briefly highlight the properties of the 41 DLAs observed in the XQ-100 survey, Figs 3 and 4 show the $\log N(\text{H I})$ and metallicity–redshift distribution (respectively) of the XQ-100 sample relative to the DLA literature sample compiled in Berg et al. (2015b). The metallicities ($[\text{M}/\text{H}]$; see Table 3) were derived following a similar scheme outlined in Rafelski et al. (2012), where they choose (in order of decreasing preference) S, Si, Zn, and Fe as the metallicity tracer. They add a +0.3 dex correction to Fe to account for the difference in observed $[\alpha/\text{Fe}]$. We adopt the Asplund et al. (2009) solar scale for all metallicity calculations. The $\log N(\text{H I})$ distribution shows no significant deviation from what is probed by the literature DLAs; a Kolmogorov–Smirnov (KS) test of the two distributions rejects the null hypothesis at 99.2 per cent confidence.

Fig. 4 shows the metallicity distribution of the XQ-100 sample (solid red line; top panel) and the metallicity distribution as a function of redshift (bottom panel). Fig. 4 emphasizes that the XQ-100 DLAs are predominantly between redshifts $z_{\text{abs}} = 3\text{--}4.5$, and as a result appear more metal-poor than the literature (which includes the lower redshift and thus higher metallicity DLAs; Rafelski et al. 2012). A KS test rejects the null hypothesis that the metallicity distributions of the literature and XQ-100 DLA samples are drawn from the same distribution at 0.3 per cent confidence. However, when both the literature and XQ-100 samples are restricted to $z_{\text{abs}} = 3\text{--}4.5$, the KS test rejects the null hypothesis at 90.6 per cent confidence.

Using the measured z_{abs} and v_{90} for the XQ-100 DLAs, we compared the derived metallicities from the $[\text{M}/\text{H}]$ – z_{abs} – v_{90} relation in Neeleman et al. (2013) to our directly measured $[\text{M}/\text{H}]$. We find good agreement between the two metallicities (mean difference of 0.02 dex), with a root-mean-squared scatter between the two

Bolded species indicate cases of column density discrepancies between XQ-100 and the literature, and are discussed in Section B.

$\Delta N(\text{X})$ is positive when the XQ-100 column density is larger than the literature value.

metallicities (0.32 dex) that is consistent with the scatter observed in Neeleman et al. (2013, 0.37 dex).

3 DISCUSSION

3.1 The metal-poor DLA towards J0034+1639

Within the XQ-100 sample, we identified a MPDLA candidate towards J0034+1639 ($z_{\text{abs}} = 4.2507$), for which we followed up with higher resolution observations with VLT/UVES to confirm the

derived metal column densities are free from contamination (see Section 2.2 for details on observations). The column densities for this MPDLA are presented in Table 6. It is interesting to note that, although the [Fe/H] abundance (-2.82 ± 0.11) is the third lowest observed to date in a DLA (Cooke et al. 2015, and references therein), its metallicity using the Rafelski et al. (2012) scheme is much higher ($[\text{M}/\text{H}] = -2.40 \pm 0.11$; 23rd lowest).

Table 7 shows the abundances for the metal-poor DLA towards J0034+1639, compared to the mean abundance derived from the metal-poor DLAs ($\langle [\text{X}/\text{O}]_{\text{MPDLA}} \rangle$) from the MPDLA sample in

Figure 2. Velocity profiles of the UVES spectrum towards J0034+1639 ($z_{\text{abs}} = 4.25$). Vertical dashed lines represent the velocity limits of the AODM integration.

Cooke et al. (2011). The abundance ratios (relative to O) of C, Si, and Fe are consistent⁶ with the typical MPDLA abundance pattern (although we note that $[\text{Si}/\text{O}]$ is almost 0.2 dex larger than the typical MPDLA measurement), implying consistency with yields from low-energy supernovae (Heger & Woosley 2010; Cooke et al. 2011). Unfortunately, we are unable to place strong constraints on Ni and other Fe-peak abundances ($[\text{Ni}/\text{Fe}] < 1.26$), which Cooke et al. (2013, and references therein) have demonstrated to be a key discriminator of the supernovae energy.

3.2 Multiple DLAs

Previous work by Lopez & Ellison (2003) on three MDLA systems found a slight deficit of $[\alpha/\text{Fe}]$ relative to the typically observed DLA. They suggested that the low $[\alpha/\text{Fe}]$ is due to environmental effects truncating star formation. With the large increase in DLA abundance measurements over the past decade, the robustness of these results can be tested. Following Lopez & Ellison (2003), we identified MDLAs in the XQ-100 and in the Berg et al. (2015b) literature DLA samples as systems of two or more absorbers within $500 \text{ km s}^{-1} \leq \Delta v \leq 10\,000 \text{ km s}^{-1}$ of each other. 6 and 21 MDLAs from the XQ-100 and the literature samples (respectively) were

identified (Table 1). Using the measured $[\alpha/\text{Fe}]$ from literature and XQ-100 DLAs, we tested the potential enhancement by comparing each MDLA galaxy with a control-matched sample of intervening DLAs from the literature sample. The control matching technique accounts for the intrinsic evolution of similar DLAs, allowing a comparative test of different environments.

The control matching was completed for each MDLA by selecting all DLAs within the pool of literature DLAs with a redshifts and metallicity identical to the MDLA, within a prescribed tolerance. We impose that the DLA control pool are not classified as MDLAs or PDLAs ($\Delta v < 5000 \text{ km s}^{-1}$). The matching tolerance for metallicity was set by the error in the MDLA's metallicity. The matching tolerance for redshift was adopted based on the known redshift evolution of mean metallicity ($[\text{M}/\text{H}] \propto -0.2 z_{\text{abs}}$; Pettini et al. 1997; Rafelski et al. 2012, 2014). The error in metallicity provides a relative spread in redshifts for a DLA to have undergone a similar metal-enrichment history. Using the slope of the redshift-metallicity evolution, we calculate the redshift tolerance (δz_{abs}) using $\delta z_{\text{abs}} = \frac{\delta[\text{M}/\text{H}]}{0.2}$, where $\delta[\text{M}/\text{H}]$ is the error in the metallicity of the MDLA.

To ensure a representative control-matched sample, we required that each MDLA had at least five matched control DLAs. Each of the matched control DLAs must have at least five detections of both Si and Fe to compute $[\alpha/\text{Fe}]$. If these criteria were not met within the initial tolerances, the size of the two matching criteria are repeatedly

⁶ We suspect the $[\text{C}/\text{O}]$ ratio is likely consistent with the typical MPDLA values, as the C II absorption is mildly saturated (see Fig. 2).

increased in small increments until a sufficient number of control matched DLAs were obtained. The metallicity bin grew by ± 0.025 dex increments (15–25 per cent of the typical error in metallicity), while the redshift criteria grew by ± 0.125 (~ 20 per cent of the associated error due to metallicity evolution). However, expansions were stopped after 10 iterations to ensure that the control-matched sample still resembles the MDLA, effectively matching within $\sim 3\sigma$ of z_{abs} and $[\text{M}/\text{H}]$. These criteria result in controls samples being identified for all MDLAs, with only three MDLAs requiring more than two expansions. The median number of matched control DLAs is 14 per MDLA, with 25 per cent of MDLAs having 19 or more (up to 37) control DLAs matched.

The left-hand panel of Fig. 5 shows the relative change of $[\alpha/\text{Fe}]$ ($\Delta[\alpha/\text{Fe}]$) in MDLAs compared to their control-matched counterparts, as a function of $N(\text{H I})$. $\Delta[\alpha/\text{Fe}]$ is computed as the difference in $[\text{Si}/\text{Fe}]$ between the MDLA absorber and median $[\text{Si}/\text{Fe}]$ of the control-matched DLAs, such that a positive $\Delta[\alpha/\text{Fe}]$ implies that the MDLA has a higher $[\alpha/\text{Fe}]$ than its control sample. Note that, although all MDLAs are matched, only 14 of the 27 MDLAs have measured $\Delta[\alpha/\text{Fe}]$ due to lack of Si and Fe column densities. Although Fe is depleted onto dust, the relative comparison of $[\alpha/\text{Fe}]$ of MDLAs and control DLAs at a fixed metallicity should remove the effects of dust depletion, as the depletion of refractory elements appears to scale with metallicity in DLAs (e.g. Pettini et al. 1997; Ledoux et al. 2002; Prochaska & Wolfe 2002; Berg et al. 2015b). For reference, the MDLAs from Lopez & Ellison (2003) are shown as large squares, and are included in the analysis. The grey points are the measured $\Delta[\alpha/\text{Fe}]$ from repeating the matching procedure on all control DLAs. The errors on the MDLA points were derived from the spread in the $[\alpha/\text{Fe}]$ of the control sample using the jackknife technique;

$$\sigma_{\text{jack}} = \sum_{i=1}^N \sqrt{\frac{N-1}{N} (\text{med}(N) - \text{med}(N-1))^2}, \quad (3)$$

where N is the number of DLAs, $\text{med}(N)$ is the median of the entire sample, and $\text{med}(N-1)$ is the median of the sample with the

**Figure 3.** The normalized $\log N(\text{H I})$ distribution of the XQ-100 (red bars) and literature DLA (Berg et al. 2015b, black dashed line) samples.

i th DLA removed. The colour of the MDLA points indicates the velocity separation of the MDLAs from their counterpart (Table 1). The median $\Delta[\alpha/\text{Fe}]$ (and σ_{jack}) for the MDLAs and control sample are 0.06 ± 0.01 dex and -0.01 ± 0.00^7 dex (respectively).

The right-hand panel of Fig. 5 shows the distribution of $\Delta[\alpha/\text{Fe}]$ for both the MDLA and control samples. The p -value from the Anderson–Darling (AD) test (p_{AD})⁸ rejects the null hypothesis that the two samples are drawn from the same parent sample at ~ 31 per cent confidence, suggesting MDLAs likely do not show any deficit (or enhancement) in $[\alpha/\text{Fe}]$ relative to the typical DLA.

⁷ σ_{jack} is much smaller than 0.01 dex, and is thus quoted to be 0 dex.

⁸ We preferentially use the AD test over a KS test as the AD test is independent of the shape of the distribution, and is more sensitive to discrepancies in the tails of the distribution.

Figure 4. Top panel: the metallicity distribution of the XQ-100 DLAs. The solid red line outlines the total metallicity distribution of the XQ-100 sample, whereas the shaded regions within each bin show the distribution of elements used as the metallicity indicator for the DLAs. The metallicity distribution of the literature DLA sample is shown by the black dashed line. Bottom panel: the distribution of the XQ-100 (red circles) and literature DLAs (black points) in metallicity–redshift space.

^aMean MPDLA abundance from Cooke et al. (2011).

We note that the Berg et al. (2015b) literature sample includes surveys that have purposefully observed DLAs of specific properties and may have a biased representation of these properties, such as high or low metallicity. As a test of robustness of these results, we limited the control-matched samples to DLAs from the relatively unbiased Rafelski et al. (2012) literature sample, and re-computed $\Delta[\alpha/\text{Fe}]$. Only 6 of the 27 MDLAs were matched, and still showed no deficit in $[\alpha/\text{Fe}]$ ($p_{\text{AD}} \sim 0.86$).

We note that the upper velocity limit of MDLAs defined in Lopez & Ellison (2003, 10 000 km s^{−1}) is much larger than the typical galaxy cluster velocity dispersion (values are typically smaller than 2000 km s^{−1}; Ruel et al. 2014). Reducing the definition of an MDLA to a separation of 2000 km s^{−1} limits the sample to one MDLA system, which shows a $\Delta[\alpha/\text{Fe}]$ of $\sim +0.2$ dex. Unfortunately more MDLAs are required to further test if a smaller velocity separation does have an impact on the MDLA abundances.

3.3 Proximate DLAs

The XQ-100 DLA catalogue from Sánchez-Ramírez et al. (2016) showed that five DLAs are PDLAs ($\Delta v \leq 5000$ km s^{−1} from the host QSO). The properties of the complete set of associated absorbers

Figure 5. The relative change in $[\alpha/\text{Fe}]$ for MDLAs ($\Delta[\alpha/\text{Fe}]$) as a function of $\log N(\text{H I})$. The left-hand panel shows $\Delta[\alpha/\text{Fe}]$ in MDLA sightlines compared to the control-matched sample (small grey points). For reference, the MDLAs observed in Lopez & Ellison (2003) are shown as large squares. The colour of the MDLA points represent the velocity separation of the DLAs along the sightline. The right-hand panel shows the distribution of $\Delta[\alpha/\text{Fe}]$ for the MDLA (red) and control (grey) samples. The p -value from the AD test for the two MDLA samples relative to the control sample is displayed; suggesting that the MDLA and control DLAs are likely drawn from the same parent sample.

in XQ-100, not just limited to DLAs, can be found in Perrotta et al. (2016). With the addition of 41 PDLAs in the literature sample (Berg et al. 2015b), we test the effect of proximity of a DLA to its host QSO for 46 absorbers. Improving upon the analysis of 16 PDLAs in Ellison et al. (2010), we compare the relative abundance of a given PDLA to a control-matched sample of intervening DLAs.

The control matching was undertaken in an identical manner as for the MDLAs, with the exception that DLAs were matched by $\log N(\text{H I})$ and redshift. In addition, we require the control sample to have at least five measured abundances for each of the following elements: S, Si, Fe, and Zn.⁹ The tolerance for the $\log N(\text{H I})$ match was set by the error in the PDLA's $\log N(\text{H I})$. If required, the $\log N(\text{H I})$ selection tolerance grew by ± 0.025 dex increments (15–25 per cent of the typical error). The same criteria for redshift used for the MDLAs was imposed for the PDLAs as well. This matching procedure resulted in successful matches for all 46 PDLAs, with 25 PDLAs being matched within three expansions, and six PDLAs requiring nine expansions. Each PDLA had at least 12 control matches. The median number of matched controls is 35.5 per PDLA, with 25 per cent of PDLAs having 52 or more controls matches.

The main science result from the control-matching analysis for PDLAs is presented in Fig. 6. We define $\Delta[X/\text{H}]$ as the difference in the PDLA abundance $[X/\text{H}]$ relative to the median abundance

⁹ The requirement of having five abundances for each element is the most restrictive criterion; but is required to ensure that DLAs are compared to the same control pool for each element. Without this criterion, all matching is completed within at most four expansions.

Figure 6. First column: the relative change in PDLA abundance compared to a sample of DLAs matched in redshift and $\log N(\text{H I})$ ($\Delta[X/H]$) as a function of $\log N(\text{H I})$. Each row is $\Delta[X/H]$ for S, Si, Fe, and Zn (top to bottom). The notation is the same as Fig. 5. In all panels, we highlight the data from Ellison et al. (2010) as large squares for comparison. Second column: the fractional distribution of $\Delta[X/H]$ for each element in PDLAs (red line) and the control sample (grey shaded region). Third column: the fractional distribution of $\Delta[X/H]$ for each element, restricting both samples to DLAs with only $\log N(\text{H I}) < 21.0$. Fourth column: the fractional distribution of $\Delta[X/H]$ for each element, restricting both samples to DLAs with $\log N(\text{H I}) > 21.0$. All PDLA distributions are compared to the control-sample distribution using the AD test, showing the p -value (p_{AD}) that the two distributions are drawn from the same parent sample.

of control-matched sample; such that a negative $\Delta[X/H]$ would imply that the PDLA has a lower $[X/H]$ than the control-matched sample. The left-most panels of Fig. 6 show $\Delta[X/H]$ as a function of $\log N(\text{H I})$ for elements (in order from top to bottom rows) S, Si, Fe, and Zn. The error bars represent σ_{jack} of the control-matched sample. The colour of the points indicate the velocity separation (Δv ; km s^{-1}) from the host QSO. PDLAs from Ellison et al. (2010) are shown as large squares, and are included in the analysis. For

comparison to the DLAs in the control pool, the smaller grey points are the $\Delta[X/H]$ obtained from repeating the control match on all control DLAs. The left-hand panels of Fig. 6 visually hint at a possible deficit of $[X/H]$ for PDLAs with $\log N(\text{H I}) \lesssim 21.0$, and an enhanced $[X/H]$ at $\log N(\text{H I}) \gtrsim 21.0$ (the enhancement was first identified for $[\text{S}/\text{H}]$ and $[\text{Si}/\text{H}]$ in Ellison et al. 2010).

To quantitatively test the possibility of a correlation between $\Delta[X/H]$ and $\log N(\text{H I})$ in PDLAs, we performed the Pearson-

Figure 7. The frequency (of 10 000 iterations) of observing a median $\Delta[X/H]$ in a randomly selected control sample of the same size as the PDLA sample. Each row is for the elements S, Si, Fe, and Zn (top to bottom; respectively), while each column is the $\log N(\text{H I})$ cut on the sample [all $N(\text{H I})$, $\log N(\text{H I}) < 21.0$, and $\log N(\text{H I}) > 21.0$; left to right, respectively]. The red band indicates the median $\Delta[X/H]$ of the PDLA sample, whose half-width is given by σ_{jack} of the PDLA $\Delta[X/H]$. The probability (p) of observing a median $\Delta[X/H]$ of the same magnitude (or further offset from 0) as the PDLA median $\Delta[X/H]$ is displayed.

test. However, the test did not show any significant correlation of $\Delta[X/H]$ with $\log N(\text{H I})$ ($r = 0.33, 0.18, 0.08, 0.00$ for S, Si, Fe, and Zn; respectively). Despite the lack of correlation, the AD statistic will additionally constrain whether the PDLAs are drawn from a different distribution of $\Delta[X/H]$ compared to the intervening control DLAs. The AD test was performed in three regimes: all $\log N(\text{H I})$, $\log N(\text{H I}) < 21.0$, and $\log N(\text{H I}) > 21.0$. The distributions of $\Delta[X/H]$ (along with the associated p_{AD}) for each regime is displayed in the second, third, and fourth column of Fig. 6 (respectively). The p_{AD} measurements suggest that PDLAs are likely drawn from a different distribution than the control DLAs for [S/H] (null hypothesis rejected at ~ 6 per cent confidence) and [Fe/H] (~ 32 per cent confidence) for $\log N(\text{H I}) < 21.0$, as well as [S/H] (~ 14 per cent confidence) and [Si/H] (~ 26 per cent confidence) for $\log N(\text{H I}) > 21.0$.

As with the MDLAs, we attempted to assess the potential biases of using the Berg et al. (2015b) literature DLAs by only adopting control DLAs from the Rafelski et al. (2012) sample. Unfortunately only two PDLAs were matched at $\log N(\text{H I}) > 21.0$, and are unable to test how robust the results are. Similarly for $\log N(\text{H I}) < 21.0$, only seven PDLAs had measured $\Delta[\text{S}/\text{H}]$, six of which had $\Delta[\text{S}/\text{H}] \leq 0$. Again, we note that by matching $\log N(\text{H I})$ should remove any effects caused by H I selection of control sample DLAs; whilst taking the median value of the control sample should remove any outlying DLAs. A larger unbiased sample of DLAs is required to further evaluate the robustness of our results.

To test whether the $\Delta[X/H]$ offsets seen in PDLAs could occur by chance in a sample of this modest size, we ran a Monte Carlo simulation with 10 000 iterations, drawing a random sample of control DLAs¹⁰ of the same size as the PDLAs sample for each element and $\log N(\text{H I})$ cut. At each iteration, we computed the obtained median $\Delta[X/H]$ for each $\log N(\text{H I})$ criteria. The distribution of obtained medians is shown in Fig. 7. To understand the likelihood of observing such an offset by chance, we calculated the frequency of observing a median $\Delta[X/H]$ that is identical or further offset from zero than the median $\Delta[X/H]$ observed for the PDLAs. Table 8 provides the median $\Delta[X/H]$ of the PDLA sample, and summarizes the frequencies of this simulation for all four elements.¹¹ The deficit of [S/H] and [Fe/H] for $\log N(\text{H I}) < 21.0$ was seen 3.2 and 5.4 per cent of the time (respectively), suggesting it is unlikely the deficit in the observations is observed by random chance. The excess of [S/H] at $\log N(\text{H I}) > 21.0$ is also unlikely to be caused by random chance, since *none* of the iterations demonstrated a similar

¹⁰ The randomly generated sample in each iteration does not contain the same DLA more than once; however, the same DLA can appear in the samples of other iterations.

¹¹ To estimate the uncertainty on the simulation, we recomputed the frequencies of observing a $\Delta[X/H]$, taking into account the σ_{jack} of the PDLA $\Delta[X/H]$ to make the offset weaker. These recomputed frequencies are provided in parentheses in Table 8.

Table 8. Frequencies of obtaining median PDLA $\Delta[X/H]$ from control DLA resampling.

median of $\Delta[\text{S/H}]$. The excess of $[\text{Si/H}]$ is seen slightly frequently 9.7 per cent of the time. Therefore there is observational evidence that PDLAs exhibit different abundances than intervening DLAs.

We now consider the possible source of distinct abundances between PDLAs and intervening systems. The deficit of S and Fe in PDLA abundances at low $\log N(\text{H I})$ might arise from ionization effects as the hard ionizing spectrum of the quasar is more likely to penetrate the self-shielding effect of DLAs at low $\log N(\text{H I})$. A natural assumption might be that PDLAs closer to the QSO ($\Delta v \leq 1500 \text{ km s}^{-1}$; Ellison et al. 2010) may be more influenced by the higher radiation field. The mean and scatter in $\Delta[\text{S/H}]$ and $\Delta[\text{Si/H}]$ for $\log N(\text{H I}) < 21.0$ is the same across all Δv , suggesting that the velocity separation of a PDLA has little effect.

It is worth noting that the uncertainty in QSO's systemic z_{em} can be large (depending on which emission lines are used; e.g. Gaskell 1982; Tytler & Fan 1992), leading to a scatter in Δv determinations from tens to a couple of hundred km s^{-1} (for QSOs identified with the Sloan Digital Sky Survey; see Ellison et al. 2010; Hewett & Wild 2010; Pâris et al. 2011). In addition, the error in z_{abs} for the DLAs will also contribute to the precision of the Δv measurements. For the XQ-100 sample, the scatter in z_{abs} derived from H I absorption (Table 1) and the metal lines is $\pm 47 \text{ km s}^{-1}$. However, the lack of a strong correlation between $\Delta[X/H]$ and Δv suggests that higher precision measurements Δv are not required.

To further test ionization effects at $\log N(\text{H I}) < 21.0$, the observed $\Delta[X/H]$ were compared to abundance discrepancies observed in QSO-like radiation models from the literature. Both Vladilo et al. (2001) and Rix et al. (2007) modelled the effect of radiation fields (for a variety of ionization strengths U) on abundances in DLAs; with their ionization abundance corrections shown in Table 9 (where positive corrections imply the observed abundances are underestimated relative to the true value). As a reference, the soft stellar-like ionizing spectrum (denoted by ^S in Table 9) from Vladilo et al. (2001) is also included. For a hard, QSO-like ionizing field (flagged by ^H in Table 9); Vladilo et al. (2001) found that $[\text{Fe/H}]$ is *over-predicted* by a factor of 0.01–0.04 dex; whereas we are finding that $[\text{Fe/H}]$ is *underestimated* in PDLAs. The corrections for the single

PDLA modelled by Rix et al. (2007) are qualitatively similar. Both sets of models suggest that the deficit of $[\text{Fe/H}]$ in PDLAs *cannot* be explained by ionization; and we rule out ionization as a possible explanation. However, the deficit for $[\text{S/H}]$ could be explained by ionization corrections for $\log N(\text{H I}) < 21.0$; but not for the excess seen at $\log N(\text{H I}) > 21.0$ (Ellison et al. 2010).

A suggestion in Ellison et al. (2010) is that PDLAs are typically probing more massive galaxies (relative to intervening systems). To test this explanation for the metallicity effect we are seeing, we checked whether the v_{90} parameter (a proxy for mass in DLAs; Prochaska & Wolfe 1997; Ledoux et al. 2006; Møller et al. 2013; Neeleman et al. 2013) is substantially larger in PDLAs than in the control sample. In addition to the v_{90} measurements of the XQ-100 sample (Table 4), we also adopt the 139 v_{90} measurements from HIRES data for DLAs in the literature (Neeleman et al. 2013; Berg et al. 2015a) for the control-matched sample.

Fig. 8 shows the difference in v_{90} for a PDLA relative to its control matched sample (Δv_{90} ; a positive value implying the PDLA has a large v_{90} than the matched controls). Again, the smaller grey points show the scatter within the control sample. There is no significant discrepancy between the v_{90} in PDLAs relative to the control, suggesting no dependence on mass; assuming v_{90} is a good proxy for mass.

3.4 [Zn/Fe] and dust depletion

Dust depletion plagues DLA abundance analysis work, making it difficult to disentangle nucleosynthetic patterns from dust depletion effects. In particular, a dust-free Fe peak tracer is necessary to measure the intrinsic $[\alpha/\text{Fe}]$ ratio, an important tracer of star formation history (Tinsley 1979; Venn et al. 2004; Tolstoy et al. 2009). In general, the community has either used elements that are relatively unaffected by depletion (such as S and Zn; e.g. Pettini et al. 1997; Centurión et al. 2000; Vladilo et al. 2011) or modelled dust depletions based on chemical evolution assumptions (e.g. Vladilo et al. 2011). One of the most prominent assumptions is that Zn is a dust-free proxy of the Fe peak (Pettini et al. 1994, 1997;

Figure 8. Left-hand panel: the difference in v_{90} between a given PDLA and control-matched sample (Δv_{90}), as a function of $\log(N(\text{H I}))$. The notation is the same as Fig. 5. Right-hand panel: distributions of Δv_{90} for the PDLA sample (red line) compared to the control sample (grey bars). The AD p -value is shown for the comparison of the two distributions.

Vladilo 2002a,b). The assumption that Zn traces Fe was motivated by early observations of Galactic stellar abundances showing $[\text{Zn}/\text{Fe}] \sim 0$ over a range of metallicities (Snedden & Crocker 1988; Sneden, Gratton & Crocker 1991; Chen et al. 2004; Nissen et al. 2004).

However, with the search for metal-poor stars extending to lower metallicities (e.g. Prochaska et al. 2000; Nissen et al. 2007), stellar $[\text{Zn}/\text{Fe}]$ showed deviations from solar suggesting that Zn does not necessarily trace Fe; leading some authors to question whether Zn traces Fe in DLAs (such as Prochaska & Wolfe 2000; Nissen & Schuster 2011; Rafelski et al. 2012). Recently, Berg et al. (2015b) compared $[\text{Zn}/\text{Fe}]$ in stars in the Milky Way and local dwarf spheroidal (dSph) galaxies, finding a large scatter of $[\text{Zn}/\text{Fe}]$ at $-2.0 < [\text{Zn}/\text{H}] < -0.5$. In particular, many (but not all) Local Group dwarf galaxy stars exhibit subsolar $[\text{Zn}/\text{Fe}]$ indicating that Zn is not necessarily a nucleosynthetic tracer of the Fe-peak elements at $[\text{Zn}/\text{H}] \geq -1.5$. In order to investigate the possibility of intrinsically non-solar $[\text{Zn}/\text{Fe}]$ ratios, Berg et al. (2015b) infer the dust-corrected values of $[\text{Zn}/\text{Fe}]$ using a novel method. Rather than using modelled corrections which require assumptions about the nature of DLAs (such as Vladilo et al. 2011), Berg et al. (2015b) assume that all α -elements trace each other in DLAs, and that the measured ratio of two α -elements may be a tracer of dust depletion. Using the relative depletions seen towards Galactic ISM sightlines (Savage & Sembach 1996), they suggest that $[\text{Si}/\text{Ti}]$ should have the same depletion correction as $[\text{Zn}/\text{Fe}]$, and can be used to correct the $[\text{Zn}/\text{Fe}]$ abundance for depletion to within 0.1 dex.

Although the Berg et al. (2015b) analysis of dust corrected $[\text{Zn}/\text{Fe}]$ is strongly suggestive of subsolar ratios in DLAs, their analysis was limited to the 43 systems (of which only 10 were detections) for which Ti measurements are available. This limitation is driven by typically only covering the weak $\text{Ti II } 1910 \text{ \AA}$ line in optical spectra for the majority of the DLA sample. Previous surveys of Mg II abundances with high-resolution spectroscopy have been

limited to $z_{\text{abs}} \sim 2\text{--}3$ DLAs (e.g. Prochaska et al. 2003; Dessauges-Zavadsky et al. 2006; Prochaska et al. 2007; Noterdaeme et al. 2008). With the additional IR coverage that X-Shooter provides, we have unprecedented access to absorption lines of α -elements that are not typically observed in the optical; particularly in absorbers at redshifts 3–4. These lines include: Mg, Ca, as well as stronger Ti lines (relative to $\text{Ti II } 1910 \text{ \AA}$; $\text{Ti II } \lambda 3073 \text{ \AA}$, $3242 \text{ \AA}$, and $3384 \text{ \AA}$).

With the XQ-100 DLA sample we are thus able to further test the intrinsic $[\text{Zn}/\text{Fe}]$ ratio of DLAs, by using the new Ti II abundances, as well as other α -elements ratios ($[\text{Mg}/\text{Si}]$ and $[\text{Ca}/\text{Si}]$) as additional dust-depletion proxies. Fig. 9 shows the DLA dust-corrected $[\text{Zn}/\text{Fe}]$ abundances (coloured circles) as a function of metallicity using $[\text{Si}/\text{Ca}]$ (left-hand panel), $[\text{Si}/\text{Mg}]$ (middle panel), and $[\text{Si}/\text{Ti}]$ (right-hand panel). For reference, the Galactic (grey points) and dSph (grey squares) stellar trends of $[\text{Zn}/\text{Fe}]$ are shown in each panel.

The difficulty of using Mg II and Ca II is that the differential depletion of $[\text{Si}/\text{Ca}]$ and $[\text{Si}/\text{Mg}]$ is much different than $[\text{Zn}/\text{Fe}]$ (differences of $+0.8$ and -1.4 dex in Galactic ISM sightlines, respectively; Savage & Sembach 1996). The two horizontal dashed lines in each panel constrain the region where the dust-corrected $[\text{Zn}/\text{Fe}]$ could be consistent with solar $[\text{Zn}/\text{Fe}]$ based on the differential depletion of $[\alpha/\text{Si}] - [\text{Zn}/\text{Fe}]$ in the Milky Way; where DLA points below the lowest line are consistent with intrinsically subsolar $[\text{Zn}/\text{Fe}]$, and DLA above the higher line likely have supersolar $[\text{Zn}/\text{Fe}]$.

The addition of Ti abundances from the XQ-100 DLA sample (red circles) does not provide any additional information on the intrinsic nature of $[\text{Zn}/\text{Fe}]$ in DLAs previously identified by (Berg et al. 2015b, blue circles). One of the XQ-100 DLAs has a dust-corrected $[\text{Zn}/\text{Fe}] \sim 0.3$ dex. Although supersolar, this one system is consistent with both Milky Way and dSphs stellar $[\text{Zn}/\text{Fe}]$ abundances (Berg et al. 2015b). Although the Ti II lines accessible in the NIR are nominally stronger than those in the optical, the typical detection limits of Ti II from the lower resolution X-Shooter spectra are not as sensitive as the measurements available from UVES or HIRES. It is worth noting that of the 38 cases Ti II abundances were measured in the XQ-100 DLAs, 28 abundances were preferentially adopted based on the Ti II lines in the NIR arm rather than the $\text{Ti II } \lambda 1910 \text{ \AA}$ line. Therefore, the use of X-Shooter to observe lines in the NIR can be a useful tool to obtain (more constraining) Ti II abundances.

The additional five Ca II robust upper limits (to the single detection in the literature) in the left-hand panel of Fig. 9 further support that DLAs span the same range of $[\text{Zn}/\text{Fe}]$ as dSphs seen by Berg et al. (2015b), suggesting that DLAs share a similar nucleosynthetic history as Galactic dSphs. However, we note that Ca II (excitation potential of 11.87 eV) is not the dominant ionization state of Ca in DLAs (e.g. Wild, Hewett & Pettini 2006), suggesting that the measured $N(\text{Ca II})$ may require significant ionization corrections.

4 SUMMARY AND CONCLUSIONS

The sample of XQ-100 DLAs provides coverage of the relatively moderately sampled redshift range $z_{\text{abs}} = 3\text{--}4$. We have computed the column densities for a variety of metals in the 41 DLAs in the XQ-100 sample. The additional coverage from the NIR arm of X-Shooter provides coverage of rarely detected lines at redshifts 3–4 in abundance studies such as Mg II , Ca II , and strong Ti II lines. With the addition of dust-depleted α -elements, we are able to test the dust-corrected $[\text{Zn}/\text{Fe}]$ to see if $[\text{Zn}/\text{Fe}]$ is solar in DLAs. We have shown in Section 3.4 that $[\text{Zn}/\text{Fe}]$ is not necessarily solar in

Figure 9. Dust-corrected $[Zn/Fe]$ DLA abundances (XQ-100 are in red, literature DLAs in blue) relative to stellar $[Zn/Fe]$ (grey points are the Milky Way, dark grey squares are dSphs) from Berg et al. (2015b). Larger, filled DLA circles represent detections, whereas the unfilled circles are limits. The dust correction is determined by subtracting the ratio of two α -elements of different relative dust depletions ($[Si/Ca]$ left panel; $[Si/Mg]$ middle panel; $[Si/Ti]$ right panel). The two dashed lines bound the region where $[Zn/Fe]$ may be consistent with solar, such that measurements below the line are consistent with subsolar $[Zn/Fe]$. In addition to $[Si/Ti]$, $[Si/Ca]$ can also constrain the intrinsic $[Zn/Fe]$ in DLAs. Both of these ratios indicate that DLAs are consistent with the subsolar values seen in dSphs (Berg et al. 2015b). This subsolar $[Zn/Fe]$ is likely nucleosynthetic in origin.

DLAs, and that $[Zn/Fe]$ shows the same range of values as seen in the dSphs of the Local Group (in agreement with Berg et al. 2015b).

In combination with a sample of DLAs drawn from the literature, we have provided a statistical analysis of PDLAs (within $\Delta v \leq 5000 \text{ km s}^{-1}$ of the host QSO) and MDLAs (two or more DLAs separated by $500 \leq \Delta v \leq 10000 \text{ km s}^{-1}$) by comparing to a control-matched sample of individual, intervening absorbers. We do not find any suppression in $[\alpha/Fe]$ in MDLAs, suggesting that there is no evidence for truncated star formation between nearby DLAs on their abundance. Relative to a control sample of DLAs, we note a mildly elevated $[S/H]$ and $[Si/H]$ for high $\log N(H\text{I}) > 21.0$ PDLAs at (AD test rejects the null hypothesis at 14 and 26 per cent confidence; respectively), as previously seen by Ellison et al. (2010); however, we also detect a deficit in $[S/H]$ and $[Fe/H]$ (null hypothesis rejected at 6 per cent and 32 per cent confidence, respectively) for PDLAs with $\log N(H\text{I}) < 21.0$. These abundance discrepancies appear to be independent of velocity separation of the host QSO and the mass proxy v_{90} . It is possible to explain the deficit of $[S/H]$ at low $\log N(H\text{I})$ through ionization corrections, but not the deficit of $[Fe/H]$.

We have also presented UVES observations of three DLAs towards J0034+1639 in order to investigate an MPDLA candidate at $z_{\text{abs}} \sim 4.25$ with a $[Fe/H] = -2.82 \pm 0.11$. This MPDLA is consistent with abundances in the typical MPDLA (Cooke et al. 2011). MPDLAs such as the one towards J0034+1639 prime targets for easily detecting Ni and other discriminating elements in future follow-up observations with 30-m class telescopes.

ACKNOWLEDGEMENTS

We thank the anonymous referee for their useful comments that clarified the text. TAMB is grateful for Ryan Cooke's assistance with developing a science case for the UVES observations of the MPDLA, and discussing the results. SLE acknowledges the receipt of an NSERC Discovery Grant which supported this research. JXP is supported by NSF grant AST-1109447. SL has been supported by FONDECYT grant number 1140838 and partially by PFB-06

CATA. KDD is supported by an NSF AAPF fellowship awarded under NSF grant AST-1302093.
