## Abstract

We report here on our search for excess power in photometry of Neptune collected by the *K2* mission that may be due to intrinsic global oscillations of the planet Neptune. To conduct this search, we developed new methods to correct for instrumental effects such as intrapixel variability and gain variations. We then extracted and analyzed the time-series photometry of Neptune from 49 days of nearly continuous broadband photometry of the planet. We find no evidence of global oscillations and place an upper limit of  $\sim 5$  ppm at  $1000 \mu\text{Hz}$  for the detection of a coherent signal. With an observed cadence of 1 minute and a point-to-point scatter of less than 0.01%, the photometric signal is dominated by reflected light from the Sun, which is in turn modulated by atmospheric variability of Neptune at the 2% level. A change in flux is also observed due to the increasing distance between Neptune and the *K2* spacecraft and the solar variability with convection-driven solar p modes present.

**Key words:** planetary systems – planets and satellites: gaseous planets

**Supporting material:** animation, machine-readable table

## 1. Introduction

The solar system hosts two classes of giant planets: gas giants and ice giants. The ice giants are lower mass (Uranus and Neptune masses are less than 18 Earth masses) with smaller hydrogen–helium envelopes and exhibit strong enrichments in heavier elements. The *Kepler* Mission has aptly demonstrated that Neptune- and Uranus-sized planets are common, in fact, much more common than gas giants outside of the solar system (e.g., Burke et al. 2015). The radius and bulk density of Neptune (and Uranus) are often cited as context for the large number of exoplanet discoveries. For example, exoplanets with a radius between twice the size of Earth and that of Neptune are commonly called mini- or sub-Neptunes, and planets similar in size and mass to Neptune are considered Neptune-like, since at present we cannot ascertain whether or not these distant

mysterious objects share similar compositions, internal structure, or evolutionary history with Neptune. Understanding the formation, internal structure, atmosphere, and evolution of Neptune is thus important, not only to investigate the physical processes at play during the formation and evolution of our own solar system, but also for distant exoplanetary systems.

The *Kepler* Mission was a four-year observing campaign to search for transiting extrasolar planets, with a primary goal of determining the frequency of exoplanets with a period of less than one year as a function of radius and distance from their host stars (Borucki et al. 2010). With almost 5000 exoplanet candidates (Coughlin et al. 2015), over 2000 confirmed planets (e.g., Lissauer et al. 2014; Rowe et al. 2014; Morton et al. 2016) and counting, it is safe to say the *Kepler* Mission has been a resounding success (e.g., Bedding et al. 2011; Chaplin et al. 2011). The loss of a second reaction wheel ended the

*Kepler* Mission after four years and one day of primary mission operations. Shortly thereafter, the *K2* Mission was born. The two-wheeled *K2* mission points toward fields located along the orbital plane of the *Kepler* spacecraft to minimize torque from solar radiation pressure. In this orientation, it achieves stable pointing using the remaining two reaction wheels supplemented with semi-periodic thruster firings (Howell et al. 2014). The *Kepler* Spacecraft, in an  $\sim 371$  day orbit around the Sun has an orbital plane similar to the Earth–Sun orbit, making some solar system planets accessible by the *K2* imager. Of the giant planets, photometry of Jupiter and Saturn is problematic due to their apparent brightness, which heavily saturates the detector, but Uranus and Neptune, while still bright enough to saturate the detector, are sufficiently faint that charge bleed from saturated pixels can be sufficiently recovered from simple aperture photometry as long as the charge does not reach the edge of the detector. Thus, high quality, photon-limited photometry of a saturated source can be obtained with the 1 m aperture *Kepler* instrument (Gilliland et al. 2010).

Our goal was to monitor Neptune continuously with broadband photometry offered by the *Kepler* instrument to: study the variability of Neptune’s atmosphere (Simon et al. 2016), study the Sun as a distant star through reflected light (Gaulme et al. 2016) and, the subject of this paper, to search for potential oscillations that would enable seismology as a technique to probe the inner structure of the planet. Seismology has long been considered a potentially powerful tool for probing the interiors of the giant planets (e.g., Vorontsov et al. 1976). Like the Sun, the fluid nature of giant planets may naturally lead to the excitation of trapped acoustic modes. The internal heat flow of Jupiter, Saturn, and Neptune, respectively, represent about 67%, 78%, and 161% of the incident solar flux and the resulting deep convective motions have the potential to excite modes. Detection and analysis of such oscillations is a promising technique for constraining the core mass of a giant planet, independent of the uncertainties that plague standard interior model inversion from the gravitational harmonics. The basic theory for computing giant planet oscillation frequencies and dispersion relations has been discussed as far back as Vorontsov et al. (1976) and includes work by Mosser (1990) for Jupiter and Marley (1991) for Saturn and the more recent work of Le Bihan & Burrows (2013) that covers a range of planetary masses and radii.

Most of the efforts dedicated to the observation of oscillations of giant planets have involved Jupiter because it is the biggest, closest, and brightest target. There have been several attempts to detect Jovian oscillations using infrared photometry (Deming et al. 1989), Doppler spectrometry (Schmider et al. 1991; Mosser et al. 1993, 2000), and careful searches for acoustic waves excited by the impact of the Shoemaker-Levy 9 comet (Mosser et al. 1996; Walter et al. 1996). In most of these campaigns, the signal-to-noise ratio (S/N) was too low or instrumental artifacts were present that inhibited any positive detection. The rapid rotation of Jupiter also limits the precision these instruments were able to obtain. While some studies have presented tantalizing upper limits (e.g., Deming et al. 1989) or potential detections (Gaulme et al. 2011), no definitive detection has been established. For Saturn, Marley & Porco (1993) suggested that density perturbations arising from internal oscillation modes could alter ring particle orbits at resonances between orbital and mode frequencies, thereby launching waves in the rings. Hedman & Nicholson

(2013, 2014) confirmed this prediction, which suggests that at very low frequencies (periods of hundreds of minutes) Saturn is indeed oscillating. To date, modes have not been observed on Uranus or Neptune, nor have they been detected in radial velocity or broadband reflected light on any giant planet.

Leibacher & Stein (1981) discussed the possible source of excitation of modes in giant planets. Based on energetic arguments, Bercovici & Schubert (1987) suggested that the amplitude of Jovian modes could reach  $10\text{--}100\text{ cm s}^{-1}$ . In Deming et al. (1989) demonstrated that the mechanism proposed by Goldreich & Kumar (1988) for solar oscillations should provide negligible amplitude for acoustic modes in the case of Jupiter, mainly because of the low vertical velocity of the convection. More recently, the different claims for p mode detection on Jupiter and particularly for f modes on Saturn have led to new investigations in this field, though no definitive results. The most promising source could be the moist convection, able to generate intermittently vertical velocities up to  $100\text{ m s}^{-1}$  inside the storms. A possible coupling mechanism between storms and acoustic modes might exist and produced at the origin of acoustic oscillations at a detectable level on Jupiter and Saturn. Lightning is also invoked as a source of acoustic waves. Whether one of these mechanisms could be efficient on Neptune is an open question. Nevertheless, the absence of a convincing prediction for acoustic mode amplitudes on this planet doesn’t preclude the possibility to detect them by observations. The possibility of observations of Neptune with *K2* presented an opportunity to try.

To test whether or not global modes are both excited and detectable by the ultra-high precision, high duty-cycle, integrated disk photometry offered by *K2* on Neptune, we proposed to observe the planet. We present here the results of our photometric observations of the planet. We focus on searching the relevant portion of frequency space, corresponding to periods of about 5–50 minutes, for unexpected excess power. For a fixed albedo and radial oscillations, motion of  $\sim 4\text{ cm s}^{-1}$  at a period of 30 minutes would produce a change in the brightness of Neptune of  $\sim 1\text{ ppm}$  solely from the changing apparent size of the planet. Another detection mechanism might be feedback between atmospheric pressure perturbations and albedo, through cloud condensation effects, but such amplitude and brightness perturbation relations require further detailed analysis. Detections at ppm levels, in Fourier amplitude, have been routinely reached with *Kepler* photometry for stars fainter than Neptune. Our challenge was to attempt to overcome additional noise associated with the motion of Neptune across the *Kepler* detector, which introduced significant time-correlated noise.

In Section 2, we present an overview of the observations and raw photometric data. In Section 3, we present our reduction methods used to extract photometric time series and to correct for instrumental effects. In particular, we present a novel method to disentangle the intrinsic variability of Neptune and instrumental effects produced by the high proper-motion of Neptune relative to the background star field by treating the variability of Neptune as a Gaussian process with correlated noise. In Section 4, we examine the photometric time series to explore variability on timescales of a month to a minute with the goal of searching for and setting limits on potential oscillations intrinsic to Neptune.

**Figure 1.** Typical *K2* short-cadence image with Neptune present is shown in the top panel. A difference image is shown in the bottom panel. The bright saturated target is Neptune. The reference image was generated using images when Neptune was not captured on the subraster, thus only the background stars are removed in the difference image enabling photometry of Neptune without dilution effects from background stars. Star residuals are due to intrapixel sensitivity variations, which can be corrected for with centroid co-detrending. See the animation for a 34 s duration movie covering the Neptune field during the full 69 days of the *K2* C3 observation.

(An animation of this figure is available.)

## 2. Observations

The *K2* C3 field provided the first opportunity to observe the planet Neptune for up to 80 days with short-cadence (1 minute) sampling.<sup>24</sup> We were awarded sufficient pixel allocation from Guest Observer Programs GO3060 (PI: Rowe) and GO3057 (PI: Gaulme) to continuously monitor Neptune for 49 days. *K2* observed Neptune near quadrature; thus, Neptune was seen to rapidly move across the *K2* field, pause and reverse course, crossing hundreds of pixels in the process. The *Kepler* spacecraft was designed to keep a star positioned on the same pixel for long durations. Stable pointing reduces systematic errors in the measured brightness of a star due to effects such as intrapixel variations. While we were able to reduce systematics in the extracted photometry, the ultimate noise floor achieved was limited by the motion of Neptune across the detector. Future observations or instrument design would benefit from maintaining the image of Neptune on a constant set of the pixels.

Short-cadence target pixel files were obtained from MAST.<sup>25</sup> The Neptune short-cadence subraster was spread across 161

FITS files. Each file contained 1 column of time-series pixel data. Each target pixel file contains observations starting on 2014 November 15 and finishing on 2015 January 18. We used the program `kpixread`<sup>26</sup> (Rowe 2016, Codebase: <http://doi.org/10.5281/zenodo.60297>) to extract each column for each sequential observation and to produce a new FITS file containing the assembly of all pixels for a single exposure. In total, 101,579 short-cadence images were generated. This step was necessary to use extraction and analysis processing tools such as IRAF. The assembled images had dimensions of  $162 \times 98$  pixels. An example of an assembled image is shown in the top panel of Figure 1.

The *K2* target pixel files contain a different time stamp for each row of pixels. The difference in time stamps is to account for different photon arrival times across the detector. We adopted the mean time of all 161 rows as the reported time stamp in the assembled FITS images. The average time difference as reported in the target pixel file headers across the assembled Neptune subraster is 0.92 s. Thus, reported time-stamps for Neptune in our time series will be off by up to 0.51 s with the precise amount dependent on the position of Neptune. This error is significantly smaller than the 1 minute integration time.

<sup>24</sup> The C3 campaign had an actual duration of 69.2 days, limited by on-board data storage.

<sup>25</sup> Observations from FITS files retrieved from the Mikulski Archive for Space Telescopes (MAST).

<sup>26</sup> Available on <https://github.com/jasonfrowe>.

**Figure 2.** Centroid motion of field stars measured in the Neptune SC subraster. Larger outliers, seen every few days, are due to instrumental effects such as desaturation of reaction wheels and thruster firings, and can be corrected. The right panel shows a small time segment of PSF centroids spanning five days of spacecraft motion. Red and green markers show motion in orthogonal directions on the CCD. The abrupt changes in location are due to semi-periodic thruster firings to correct for the roll of the telescope.

We scanned through the time series of assembled short-cadence images to determine when Neptune entered and left the frame. There are  $\sim 69$  days of short-cadence observations available, but Neptune is only visible in the subraster for  $\sim 49$  days. A movie of the images was assembled that showed how the observed field changed with time. The movie (available in the animation of Figure 1) showed the star field, which revealed image jitter and several main belt asteroids that quickly move through the frame. Neptune appears 15 days after the start of the data acquisition on 2014 December 1. The *Kepler* CCD detector has pixels  $4 \times 4''$  in size, similar to the apparent size of Neptune. The image of Neptune is heavily saturated, thus significant bleed along columns covering  $\sim 20$  pixels in length was observed.

It is important to note that the charge bleed does not extend outside of the subraster or reach the edge of the detector; thus, good photometry can be extracted by aperture photometry as charge is conserved. The motion of Neptune is observed to slow down then pause on day 41, which corresponds to when Neptune, the *Kepler* spacecraft and the Sun were at quadrature. After passage through quadrature, the observed motion increases until Neptune leaves the subraster on day 65. Neptune’s faint moon Nereid tracks the planet in the movie with an offset of roughly 50 pixels to the left. The bright moon Triton orbits the planet with a separation of a few pixels, roughly every 5.9 days.

### 3. Data Reduction Methods

To extract time-series photometry of Neptune from the *K2* images, we performed the following tasks: (1) measured the positions of field stars on each short-cadence image, (2) created a reference image from images obtained during times when Neptune was not visible, (3) performed image subtraction using convolution techniques on images with Neptune present to remove field stars, and (4) estimate the position of Neptune. Photometry was measured with an aperture large enough to capture the image of Neptune, the moon Triton, and column bleed from saturation.

#### 3.1. Centroids

The positions of the field stars were observed to show motion that can be larger than a pixel. Measuring the positions was important because it allowed for the rejection of frames when significant motion was detected and also allowed for the decorrelation of photometric variability due to intrapixel sensitivity changes.

To measure centroid changes, we used the program *allmost* (Rowe et al. 2006, 2008), which was designed to extract positions and photometry from images from the *MOST* mission (Walker et al. 2003). The program fits a PSF model to all stars identified in the field-of-view. In total, 81 fields were identified and tracked. The PSF model was a two-dimensional Gaussian. The PSF was simultaneously fit to all stars in the field. The shape of the PSF was assumed to be constant across the Neptune subraster, but allowed to vary for each individual exposure. Saturated pixels were excluded from the fits. Valid centroids were extracted for 100,928 frames, a success rate of 99.3%. Some images showed extreme motion that caused the PSF fitting algorithm to fail due to significant blurring of the PSF across many pixels.

The centroids for each frame were then matched to centroids from the first acquired short-cadence image (frame 1) with a model to account for shift and rotation,

$$\begin{aligned} x_i &= S_1 + S_3 x_1 + S_5 y_1 \\ y_i &= S_2 + S_6 x_1 + S_4 y_1, \end{aligned} \quad (1)$$

where  $x_i$  and  $y_i$  are the column and row of the assembled image. The  $x$  direction represents the primary motion of Neptune across the field of view. The motion of frame,  $i$ , is relative to the first image. The coefficients  $S_1$  and  $S_2$  are the shifts in position and  $S_3$  through  $S_6$  determine the scale and rotation of the image. The shifts in row and column are shown in Figure 2, with the pixel scale chosen to show the overall scatter and timescale of the motion. The point-to-point scatter in the centroid positions demonstrates a measurement accuracy of  $\sim 0.02$  pixels. The centroids show a semi-periodic behavior of slow drift and rapid motion back to a reference position. This behavior is indicative of the operation of the two-wheeled *K2*

mission: drift due to slightly unbalanced solar force until a threshold is reached, followed by thruster operation to correct the drift.

### 3.2. Reference Image

We used the first 10,000 short-cadence images (all taken prior to Neptune entering the aperture) to create a reference image to be used for image subtraction. Images with a centroid shift greater than 0.5 pixel were excluded to minimize problems with motion smear broadening the PSF in the reference image. The reference image was created using the software tool montage2 (Stetson 1987), which handles image resampling to match image centroid changes and to create a median stacked image.

### 3.3. Image Subtraction

We used aperture photometry to extract photometry of Neptune. To mitigate dilution of the photometry from additional stars in the photometric aperture as Neptune traverses the subraster, we used convolution techniques to match a target image to a reference image and then subtract the reference image from the target image. The subtracted image will have the flux contributions from constant field stars removed, allowing for clean extraction of photometry of sources not present in the reference image, specifically, of Neptune.

With a reference and target image, we generated a convolution kernel to match the reference image to the target image. The kernel is represented as a discrete pixel array based on the method of Bramich (2008). One then solves for the kernel values directly using linear least squares. The advantage of this model is that small, subpixel image drift is automatically accounted for in the kernel solution, thus the problem of interpolation for subpixel image registration is fitted simultaneously with changes in the PSF shape. Pixels that are saturated or within a 15 pixel wide box centered on the position of Neptune were excluded from the kernel fit. To perform image subtraction, the reference and target image were co-aligned to the nearest integer pixel. Then the reference image was convolved to match the target image. The convolved image was then subtracted from the target image to produce a residual image that was used for photometry.

The position of Neptune was determined by an average of all pixel positions with saturated counts. The column position shows a point-to-point scatter of 0.1 pixels. The row positions show point-to-point scatter of 0.8 pixels. The row position accuracy is degraded because of column bleed and shows some correlation with the measured flux of Neptune.

Figure 1 shows a subtracted image at the bottom and the original image at the top. Neptune is the bright saturated object seen to the left of each image. The difference image shows that the stars are cleanly removed. Some of the brightest stars show some systematic residuals in the core of the PSF that are above the expected shot noise for subtraction by factors between 1.5 and 2. This results in a potential systematic error of 300 counts at maximum in the aperture photometry of Neptune. The median flux measured from Neptune in a single exposure was  $\sim 7.6 \times 10^6 e^-$ , thus, imperfect residuals from image subtraction have minimal impact on the photometry of Neptune because shot noise will dominate.

### 3.4. Aperture Photometry

We extracted Neptune photometry from difference image frame numbers 24103 through 96342, corresponding to dates 2014 December 1 through 2015 January 18. We used an aperture box with pixel dimensions of  $8 \times 30$ . The width was chosen to continuously capture the flux of Triton together with Neptune to avoid the problem of Triton moving in and out of the photometric aperture during its five day orbit. The height was chosen to capture column bleed across all images. The box was centered on the pixel closest to the measured position of Neptune. Valid photometry was recovered for 71,776 frames. Frames without valid centroids or motion greater than 1 pixel were excluded from the photometric analysis.

The raw photometry is shown in Figure 3. There is a linear decrease in the flux that is due to the increasing distance between the *Kepler* spacecraft and Neptune. The 2% variations with a period of 16 hr are due to the rotation of Neptune, with visible features appearing and disappearing from view (Simon et al. 2016). A close-up inspection of the data in the bottom panel of Figure 3 showed a periodic trend with a timescale of  $\sim 0.5$  day on day 16. This is due to intrapixel variations and is well traced by the column position of Neptune. Thus, the timescale of this variation is not constant. There are also sudden, abrupt changes in the flux that are correlated with column position. We think that these jumps are due to Neptune crossing a pixel boundary and saturated bleed moving to adjacent pixels with different gain. Sudden changes in the flux values were not seen for every crossing event. The bottom panel of Figure 3 shows the observed behavior we associate with pixel crossings centered on the start of day 20 with the corrections described hereafter.

### 3.5. Corrections for Instrumental Effects

We corrected for the jumps in the photometry due to pixel crossing with a piecewise line segment model. The model,  $m_i$  for each observation, can be written as,

$$m_i = \begin{cases} a_j + b_j x & \text{if } 0 < x \leq 1 \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

where  $a_j$  and  $b_j$  are fitted coefficients for the zero-point and slope for each line segment,  $j$ . A segment is defined as the data points between two identified pixel crossing jump events. The segment is defined to have a scaled length of unity, where  $x$  is a measure of the relative distance between the two observations.

Assuming Gaussian noise statistics the log-likelihood of our model matching the data is given by

$$\ln p = -\frac{1}{2} r^T K^{-1} r - \frac{1}{2} \ln \det K - \frac{N}{2} \ln 2\pi, \quad (3)$$

where  $N$  is the number of observations and  $r$  is defined as

$$r_i = f_i - m_i, \quad (4)$$

which is the difference between the photometric measurements,  $f_i$ , and our pixel jump model,  $m_i$ , for each observation index,  $i$ . The transpose of  $r$  is  $r^T$ . The co-variance matrix,  $K$ , was used to model the rotation modulation and long-term drift observed photometrically as a Gaussian process, thus each observation was associated to a normally distributed multi-variate random

**Figure 3.** Top panel shows the raw, corrected and distance-corrected photometry. The raw and corrected photometry have been arbitrarily offset by 0.11 and 0.06 in normalized flux for plotting purposes. The time is relative to the start time of short-cadence acquisition of the Neptune subraster, which corresponds to  $\text{BJD} = 2456977.09331$ . The bottom panel shows the same photometry as the top panel but from just after day 16 to day 22, representing the first  $\sim 6$  days of short-cadence photometry. The zoom showcases the corrections of the photometric variations due to intrapixel variations as seen during day 16 and pixel jumps as seen near day 20.

variable. Our correlated noise model is

$$K_{ij} = C_1 \exp\left(\frac{-(t_i - t_j)^2}{l_1^2}\right) + C_2 \exp\left(\frac{-(t_i - t_j)^2}{l_2^2}\right). \quad (5)$$

The first component was used to model the variability of Neptune driven by rotation. The second component models the long-term decrease in flux due to the increasing distance between the *Kepler* spacecraft and Neptune. The amplitude of correlated noise components is given by  $C_1$  and  $C_2$  for the rotation modulation and drift, respectively, and the timescales are given by  $l_1$  and  $l_2$  respectively.

The long-term drift is due to the increasing distance between Neptune and the *Kepler* spacecraft. The *Kepler* spacecraft has an orbital period of 371 days compared to 60,182 days for Neptune. Over the 49 days of short-cadence monitoring, the position of Neptune can be considered fixed, whereas *Kepler* will have traveled approximately 0.8 au away from Neptune. The distance is continuously increasing because observations from *K2* were obtained near quadrature. This change in distance corresponds to a 5% decrease in the apparent flux, which agrees well with the *K2* observations. This allows us to set the timescale  $l_2$  to the *Kepler* orbital period.

The rotation period of Neptune is  $\sim 16$  hr, which corresponds to the 2% variations observed with the same period. We chose an initial guess of  $l_1$  to be one-fifth of the rotation period to model the weather variability and rotation modulation (Simon et al. 2016). This choice of a timescale was motivated through a Fourier analysis of the times-series photometry showing the detection of harmonics up to the fifth order of the rotation period and still significantly longer than the sudden jumps that occur on 1 minute (or even shorter) timescales but short enough to capture the dynamic variability of Neptune.

Before we fit for the pixel jump model, we identified outliers and the temporal locations of pixel jumps. Since not every pixel crossing event produces a jump coupled with errors in the measurement of the position of Neptune, it was difficult to precisely predict when a sudden jump occurred. Outliers in the photometry occur due to image motion and cosmic-ray hits, or may even be intrinsic to Neptune. We did not attempt to identify the source of each outlier. We identified outliers by comparing the change in Neptune’s flux relative to the observation obtained right before or after,

$$\begin{aligned} v_p &= f_i - f_{i+1} \\ v_m &= f_i - f_{i-1}. \end{aligned} \quad (6)$$

If  $|v_p|$  and  $|v_m|$  were greater than a chosen threshold (0.0005) and  $v_p/v_m > 0$  then the observation was considered an outlier and discarded from further analysis.

To identify pixel jumps, we applied a bandpass filter to the time-series photometry to remove variability with timescales longer than 0.02 day. This timescale was chosen to remove variability in the light curve, but preserve the pixel jumps as excursions above and below the mean value. To identify a jump, we scanned through each time step of the detrended time series and fit a line to the previous 10 and next 10 observations independently. The two fitted lines give extrapolated estimates of the current measurement to compare to. If the difference from the forward and backward time prediction is greater than  $3\sigma$ , then a jump is detected and recorded. We estimated  $\sigma$  as the standard deviation of the detrended data after the application of the bandpass filter.

In total, we identified 146 jumps and 366 outliers. We then fit our piecewise jump model and Neptune-correlated noise model to the Neptune photometric observations after the removal of outliers. There were 296 parameters fitted: 292 parameters controlling the zero points and slopes of the line segment, 2 amplitudes for the noise model, and 2 length scales to describe the variability of Neptune in the noise model. A best-fit model was found using the L-BFGS-B code of Zhu et al. (1997, p. 550). This code is a limited memory, quasi-Newton method that approximates the Broyden–Fletcher–Goldfarb–Shanno algorithm (Press et al. 1992, p. 418). Our best-fit model was then used to correct the pixel jumps in the data.

We corrected for intrapixel variations present in the raw time-series photometry. Again, we treated Neptune variability as correlated noise but used a longer timescale of 0.17 day to avoid degeneracy between the noise model and the timescale of pixel crossings, which varies from stationary to  $\sim 10$  pixels day<sup>-1</sup>.

Our intrapixel model describes the photometric flux vs pixel location in row and column. We indexed the current row and column position as a function of time. Thus, if Neptune returns to the same pixel later in time, that pixel event is given a unique index. This allows the use of a linear model to describe the intrapixel variations and pixel-to-pixel gain variations. Our model,  $pm$ , is a series of sinusoids—one for each pixel index,  $j$ , which can be written as

$$pm_j = A_j \sin(2\pi x + \phi_j) \quad (7)$$

where  $j$  is the pixel index,  $A_j$  and  $\phi_j$  are the amplitude and phase of the correction and  $x$  is the relative column position. To avoid discontinuities in the model, we linearly interpolated the applied amplitude between adjacent pixels to create a smooth function. We use the same L-BFGS-B algorithm as above to find a best-fit intrapixel model.

The top panel of Figure 3 shows the corrected light curve for Neptune. The bottom panel of Figure 3 shows a comparison of the raw and corrected light-curves for a small segment of the data. The pixel jumps and intrapixel variations are well corrected. Table 1 contains our distance-corrected adopted time-series observations for analysis as plotted in Figure 3.

#### 4. Results

We removed the long-term trend in the corrected photometry due to the distance effect. Our adopted time-series photometry

(This table is available in its entirety in machine-readable form.)

used for the analysis is presented as the bottom light curve in Figure 3. In Figure 4, we show the power density and windowed Fourier transform of the photometric time series. The Fourier transform was computed using an FFT. The time series was resampled onto an equally spaced grid using linear interpolation, which included accounting for gaps in the time series. The data was zero-padded to achieve an oversampling a factor of five. The power density spectrum (PDS) is presented in the bottom panel of Figure 4 and reveals a few features of the variability observed from the Neptune observations:  $1/\nu$  noise, rotation modulation, and solar variability. There is a clear decrease in PDS with increasing frequency. The red line in Figure 4 is an estimate of the mean PDS (see Section 4.2 below), which shows a change in slope around  $60 \mu\text{Hz}$ . This change is likely related to the observation of two sources of variability: one intrinsic to the instrument and the other related to astrophysical processes such as solar granulation and Neptune weather. The  $1/\nu$  behavior observed for frequencies larger than  $\sim 60 \mu\text{Hz}$  is likely instrumental noise related to the motion of Neptune across the subraster and the motion of incident flux across hundreds of different pixels. The windowed Fourier transform shows a time-frequency representation of the data and is shown in the top panel of Figure 4. The figure was created using a running tapered window with a length of five days. For frequencies above  $\sim 60 \mu\text{Hz}$ , the amplitude of the noise floor is variable with time and strongly correlated with the velocity of Neptune across the detector. The lowest levels are observed near day 41, which corresponds to when the motion of Neptune is minimized. The additional noise from motion has a  $1/\nu$  dependence and ultimately sets the detection limit for frequencies shorter than  $\sim 60 \mu\text{Hz}$ .

The excess power between 10 and  $20 \mu\text{Hz}$  is the rotation modulation from Neptune (See Figure 2 from Simon et al. 2016). Localized bright clouds high in the atmosphere reflect light back toward the observer before the onset of scattering and absorption due to haze and methane deeper in the atmosphere. The clouds generally trace the zonal wind velocity and rotation period (Simon et al. 2016). The observed flux is modulated as the clouds evolve or rotate from view. The first through fifth harmonics of the rotation period were detected, showing the non-sinusoid shape of the rotation signature. Near  $3000 \mu\text{Hz}$ , there are a handful of significant frequencies detected and an excess of power centered on these frequencies is detected. This variability is due to solar p mode oscillations seen in reflected light. The detection of solar oscillations allows for the study of the Sun as a distant star as the observed signal represents an integrated disk measurement (Gaulme et al. 2016). There are two peaks at very high frequency beyond  $7000 \mu\text{Hz}$ . These are instrumental features that were first recognized in

**Figure 4.** Bottom panel plots the power spectral density (PSD) of the distance-corrected photometry. The calculation is described in Section 4. The red line shows the fitted PSD model based on Equation (8), which is an estimate of the mean. The green line is 9.89 times the PSD model and presents our adopted cut to identify significant frequencies as described in Section 4.1. The top panel shows a windowed PSD to demonstrate variability in PSD as a function of time. Light, green color represents larger values of the PSD and darker bluer colors correspond to lower values of the PSD.

short-cadence observations from the 4 year *Kepler* mission and are thought to be related to the inverse of the long-cadence ( $\sim 30$  minute) sample time. The location of these frequencies measured from *K2* observations has changed relative to the *Kepler* mission, suggesting evolution of the instrument and the root cause of this signal.

The primary goal of this paper was to search for oscillations from Neptune. The idea is that, as observed in the Sun, convection-driven p modes can have sufficient amplitude and coherence that such behavior could be detected in disk-integrated light from Neptune. While p-mode excitation in astrophysical fluids, such as that present in the Sun, is qualitatively understood (e.g., Goldreich & Kumar 1988), it should be noted that convection in gas giants may be too slow to drive oscillations (Deming et al. 1989). However, any detection of oscillation frequencies or excess power would enable the study of the interior of the planet analogous to studies of the Sun’s interior via helioseismology. The detection or the placing of a significant upper limit is also important for the planning of future instruments or observations to observe the global oscillations. The existence of resonant modes of oscillations in a planet requires a trapping mechanism for the waves. As first demonstrated by Vorontsov et al. (1976), the atmospheres of the giant planets indeed reflect acoustic waves,

but only if their frequency is below a cut-off value. Detailed calculations of the vertical propagation of acoustic waves by Mosser (1995) show that the level at which the waves are reflected is a strong function of their frequency. In all four giant planets, it turns out that most waves are reflected just below the tropopause and above the main cloud deck. In the case of Neptune, the maximum frequency for resonant acoustic modes is about  $3000 \mu\text{Hz}$  (see Gaulme et al. 2014, pp. 189–202, Figure 2). The possible acoustic waves excited at larger frequencies are not trapped by Neptune’s troposphere and get dissipated in the stratosphere. More precisely, after increasing monotonically in the upper troposphere, the cut-off frequency reaches a maximum at the tropopause and decreases to a plateau at about  $2000 \mu\text{Hz}$  in the mid-stratosphere. As analyzed by Mosser (1995) for Jupiter, it means that waves with frequencies between  $2000$  and  $3000 \mu\text{Hz}$  can leak into the troposphere by the tunneling effect, making their trapping less efficient. Regarding the lower limit, the acoustic cut-off profile shows that waves with frequencies less than  $800 \mu\text{Hz}$  are trapped deeper than pressure levels of about 10 bars. Even though radiative transfer in these planets is not fully constrained, it is very likely that optical observations do not probe that deep. Waves at frequencies lower than  $800 \mu\text{Hz}$  are thus evanescent at altitudes probed by optical observations.

**Figure 5.** Envelope of the autocorrelation function (EACF) as a function of frequency (x-axis) and time (y-axis). The EACF was computed every  $20 \mu\text{Hz}$  from 500 to  $4000 \mu\text{Hz}$ , by filtering the time series in a frequency bandpass of  $500 \mu\text{Hz}$ . The darker a region is, the larger the correlation. Solar modes are clearly visible in between  $2500$  and  $3500 \mu\text{Hz}$  at approximately  $4$ ,  $8$ , and  $13$  hr.

It is therefore reasonable to expect Neptune oscillations’ maximum amplitude to be between  $800$  and  $2000 \mu\text{Hz}$ .

Regarding the mean frequency spacing between mode overtones, it is expected to range from  $198$  to  $213 \mu\text{Hz}$  according to internal structure models (Gaulme et al. 2014, pp. 189–202). In addition, because of Neptune’s rapid rotation, acoustic modes of non-radial oscillations with azimuthal order  $m$  not equal to zero split apart into  $+m$  and  $-m$  peaks separated by  $2m$  times the inverse rotation period, i.e.,  $\approx 2m \times 17.4 \mu\text{Hz}$ .

#### 4.1. Search for Excess Power

The power spectral density (Figure 4) does not display any excess power typical of global oscillations in the  $[800, 2000] \mu\text{Hz}$  range, and nowhere else except for the solar oscillations. We also searched for Neptune’s oscillations in the envelope of the autocorrelation (EACF) of the time series, filtered in the expected frequency domain (Roxburgh & Vorontsov 2006; Mosser & Appourchaux 2009). This approach allows for us to derive the mean large separation of a solar-like oscillation spectrum in a blind way without prior information. It has been shown to be efficient in cases of low S/N (e.g., Mosser et al. 2009; Gaulme et al. 2010; Mosser et al. 2010). The reliability of the result is given by an  $H_0$  test: when the EACF is above a threshold level, the null hypothesis can be rejected, implying that a signal might have been detected.

The envelope of the autocorrelation displays a maximum in between  $1.96$  and  $2.15$  hr in the frequency range  $[600, 1400] \mu\text{Hz}$  (Figure 5). From the  $H_0$  test, the likelihood for this peak to be a signal is about 95%. This would correspond with a large frequency spacing, ranging from  $258$  to  $283 \mu\text{Hz}$  if it is the result of Neptune’s oscillations. However, if this excess of power in the autocorrelation diagram is generated by Neptune’s oscillations, we should find peaks corresponding to its rotation period ( $16$ – $17$  hr) and some harmonics, as modes are split by it. Figure 5 does not exhibit significant maxima at  $16$  or  $8$  hr. As a

**Table 2**  
Fitted Parameters

Parameter	Value	Units
$B$	$2.25 \times 10^{-2}$	$\text{ppm}^2/\mu\text{Hz}$
$A_1$	$8.32 \times 10^4$	$\text{ppm}^2/\mu\text{Hz}$
$\theta_1$	$2.55 \times 10^1$	$1/\mu\text{Hz}$
$\alpha_1$	2.28	
$A_2$	$6.01 \times 10^4$	$\text{ppm}^2/\mu\text{Hz}$
$\theta_2$	$3.63 \times 10^{-2}$	$1/\mu\text{Hz}$
$\alpha_2$	5.54	
$D$	$1.30 \times 10^{-2}$	$\text{ppm}^2/\mu\text{Hz}$
$f_{\text{max}}$	$3.25 \times 10^3$	$\mu\text{Hz}$
$\sigma$	$9.23 \times 10^1$	$\mu\text{Hz}$

**Note.** Best-fit parameters.

comparison, we displayed the correlation diagram up to frequencies including the solar oscillations. We clearly detect the Sun’s large separation, as well as secondary peaks due to the various overtones and the separation between  $\ell = 0$  and  $\ell = 1$  modes. Finally, we investigated whether a structure could be detected in the échelle diagram corresponding to a  $\approx 280 \mu\text{Hz}$  and nothing was observed, making it useless to reproduce in the paper. The signal in the  $[600, 1400] \mu\text{Hz}$  range does not show similar features, and we conclude that this 2 hr signal is likely spurious and related to incomplete corrections of instrumental signals due to the motion of Neptune.

#### 4.2. Search for Significant Frequencies

The PDS was observed to significantly drop off the  $40$ – $80 \mu\text{Hz}$  region, which is dominated by power leakage and variability associated with weather and rotation of Neptune, thus we conducted our search for significant frequencies and/or excess power on timescales shorter than  $10^4$  s (frequencies

**Figure 6.** Normalized amplitude spectrum of Neptune photometry based on our power density spectrum model, which includes fitting for excess power due to solar p modes. The green line marks our confidence level to have a false-alarm detection of less than one. The red line is a running average with a binwidth of  $30 \mu\text{Hz}$ . Significant frequencies are seen as low frequencies (less than  $100 \mu\text{Hz}$ ) due to weather and rotation of Neptune, solar modes near  $3000 \mu\text{Hz}$  and high-frequency instrumental signals between  $7000$  and  $8000 \mu\text{Hz}$ .

above  $100 \mu\text{Hz}$ ). The search for individual frequencies assumes that any such signal is coherent over a few days (as indicated by stellar oscillations, e.g., Appourchaux et al. 2008). The search for excess power assumes that an envelope of power would be produced that is similar to the observation of low-power p modes observed in the Sun.

To estimate the significance of any frequency from the Fourier analysis, we fit a semi-Lorentzian model to the observed PDS of the Neptune photometric time series. The addition of a Gaussian centered on the observed location of the solar p modes was also used to model excess power in that range. The adopted model was

$$P(f) = B + \sum_i^N \frac{A_i}{1 - (\theta_i f)^{\alpha_i}} + D \exp\left(\frac{-(f_{\max} - f)^2}{2\sigma^2}\right), \quad (8)$$

where  $B$  is the noise floor ( $\text{ppm}^2/\mu\text{Hz}$ ),  $A_i$  is the amplitude of the semi-Lorentzian,  $\theta_i$  is the characteristic timescale, and  $\alpha_i$  is the decay. The Gaussian component has an amplitude,  $D$ , centered on frequency,  $f_{\max}$  with width,  $\sigma$ . We found that  $N = 2$  components provided a reasonable fit. Best-fit parameters were obtained with a Levenberg–Marquardt chi-square minimization routine (More et al. 1980). Our best-fit parameters are listed in Table 2.

Figure 6 shows the amplitude spectrum after normalization with our power-density model. We observed that a histogram of normalized power shows a log-linear trend, this means that Gaussian chi-square statistics, which can be used to determine the probability of the power associated with any frequency, may be due to noise (Gabriel et al. 2002). Equation (12) from Gabriel et al. (2002) was used to estimate the probability of a frequency with power  $m$  times the mean,

$$P(m) = 1 - (1 - e^{-m})^{\rho N}, \quad (9)$$

with,  $N = 52429$ , the number of Nyquist sampled frequencies, and  $\rho = 2.6$  to account for five times oversampling. We solved to find  $m$  with  $P(m) = 1.9 \times 10^{-5}$ , which corresponds to a false-alarm detection of no more than one frequency of significance. We find  $m = 9.89$ , which is plotted in Figure 6.

There is a clear detection of individual solar p modes around  $3000 \mu\text{Hz}$  and the *Kepler* instrumental frequencies above  $7000 \mu\text{Hz}$ . No other frequencies above  $100 \mu\text{Hz}$  are detected. We found no candidate frequencies that could be due to intrinsic oscillations of Neptune. Using our value for  $m$ , we can place an upper limit of  $\sim 5 \text{ ppm}$  at  $1000 \mu\text{Hz}$  for the detection of a coherent signal.<sup>27</sup> Our noise limit ranges from  $\sim 100 \text{ ppm}$  at  $100 \mu\text{Hz}$  to  $\sim 2.3 \text{ ppm}$  at  $3000 \mu\text{Hz}$ . The red line in Figure 6 is a running mean with a bin width of  $30 \mu\text{Hz}$ . There is no strong evidence of excess power above  $100 \mu\text{Hz}$ . Thus, we conclude that we do not find any evidence of oscillations in broadband photometry of Neptune obtained by the *K2* mission.

For fixed albedo, a brightness change of  $5 \text{ ppm}$  is equivalent to a change in the radius of Neptune of  $62 \text{ m}$ . On a 17 minute timescale ( $\sim 1000 \mu\text{Hz}$ ) such a radius change translates to a radial velocity semi-amplitude of  $38 \text{ cm s}^{-1}$ . Our intended goal was to probe variability at amplitudes lower than  $1 \text{ ppm}$ , which would set radial upper limits of better  $8 \text{ cm s}^{-1}$ .

## 5. Summary and Conclusions

We have presented 49 days of continuous broadband photometry of the planet Neptune from the *K2* mission. The photometry shows 2% variability associated with the presence of evolving bright clouds and the rotation of Neptune. There is also a clear detection of solar p mode oscillations in reflected light, which demonstrates the overall data quality and the ability to detect oscillations with amplitudes of  $\sim \text{ppm}$  levels in the Fourier domain (Gaulme et al. 2016). Our goal was to detect oscillations intrinsic to Neptune, but our search was unsuccessful. The noise floor, while impressively low, was ultimately set by the motion of Neptune across the field of view crossing hundreds of pixels coupled with pointing jitter and pixel-to-pixel and intrapixel gain variations.

We were able to correct instrumental artifacts present in the raw *K2* aperture photometry for a moving object by using difference imaging to mitigate dilution of the photometric signal from background stars passing through a photometric

<sup>27</sup> Divide by  $\sqrt{9.89}$  to get the mean level.

aperture centered on the observed position of Neptune. Additionally, by treating the variability of Neptune as correlated Gaussian noise, we were able to model intrapixel variations and sudden changes in the photometry that were correlated with the motion of Neptune.

While our search for intrinsic convection-driven pulsations in Neptune was unsuccessful we have learned valuable lessons that can be applied to future photometric observations of solar system objects. In 2016, *K2* observed the planet Uranus, which provides a rare opportunity to obtain a long uninterrupted photometric time series of the planet to repeat our Neptune experiment: to characterize the weather and cloud timescales, to study the Sun as a distant star through reflected light and to search for intrinsic Uranus oscillations. Our experience with Neptune photometry has also taught us how to reduce the impact of instrumental effects from moving objects observed by *K2* and how to plan future missions or photometric campaigns. The obvious conclusion is that it is beneficial to keep the position of Neptune, or any target, located on the same pixel. The windowed FT in Figure 4 shows a clear decrease in the high frequency noise floor around day 25. This corresponds to when *K2* and Neptune passed through quadrature and the planet motion across the detector was minimized. A *Kepler*-like instrument capable of tracking Neptune would be capable of probing the intrinsic variability of Neptune at ppm levels on timescales of 30 minutes and shorter. Our detection limits in the Fourier domain with 49 days of broadband photometry sets a benchmark for future experiments to search for oscillation patterns with integrated disk photometry.
