ABSTRACT

Carbon is an essential element for life but how much can be delivered to young planets is still an open question. The chemical characterization of planet-forming disks is a crucial step in our understanding of the diversity and habitability of exoplanets. Very low-mass stars ($< 0.2 M_{\odot}$) are interesting targets because they host a rich population of terrestrial planets. Here we present the JWST detection of abundant hydrocarbons in the disk of a very low-mass star obtained as part of the MIRI mid-INfrared Disk Survey (MINDS). In addition to very strong and broad emission from C_2H_2 and its $^{13}C^{12}CH_2$ isotopologue, C_4H_2 , benzene, and possibly CH_4 are identified, but water, PAH and silicate features are weak or absent. The lack of small silicate grains implies that we can look deep down into this disk. These detections testify to an active warm hydrocarbon chemistry with a high C/O ratio in the inner 0.1 au of this disk, perhaps due to destruction of carbonaceous grains. The exceptionally high C_2H_2/CO_2 and C_2H_2/H_2O column density ratios suggest that oxygen is locked up in icy pebbles and planetesimals outside the water iceline. This, in turn, will have significant consequences for the composition of forming exoplanets.

M dwarfs are the most common stars in the Galaxy and are known to host exoplanets in abundance^{1,2}. However, the terrestrial planet-forming zones of the disks around M dwarfs have been largely inaccessible with previous observations due to limited spatial and spectral resolution and the dim nature of these objects. The source 2MASS-J16053215-1933159 (hereafter denoted as J160532) is a member of the ~ 3 –11 Myr old Upper Scorpius star forming region at a distance of 152 ± 1 pc³, with an age of 2.6 ± 1.6 Myr⁴. Its spectral type of M4.75 points to a very low-mass young star ($M_* = 0.14 M_{\odot}$, $L_* = 0.04 L_{\odot}$)^{5–7} that is still undergoing accretion at a rate of $\sim 10^{-10} - 10^{-9} M_{\odot} \text{ yr}^{-1}$. Its broadband infrared spectral energy distribution (SED) indicates the presence of circumstellar material in the form of a disk-like structure in which planets could originate. The non detection of millimeter continuum emission⁸ suggests that the current disk mass in millimeter-sized grains is less than $0.75 M_{\text{Earth}}$. For a standard gas/dust ratio of 100, this would imply a gas mass that is less than 20% of that of Jupiter.

We observed J160532 with the JWST MIRI⁹ Medium Resolution Spectrometer (MRS) with a spectral resolving power $R \sim 1500$ –4000 covering 5–28 μm as part of the guaranteed time MIRI mid-INfrared Disk Survey (MINDS) (see Methods section for more details). The continuum subtracted 5–18 μm part of the MIRI spectrum is presented in Figure 1. Compared with mid-infrared spectra of other disks around low-mass stars obtained with the *Spitzer* Space Telescope [10, 11, e.g.], its shape is unusual⁷. The broad wavelength spectrum clearly shows two strong, broad bumps centered at 7.7 μm and 13.7 μm , not seen toward any other disk so far¹². In contrast, no clear silicate emission features are found at 10 μm and 18 μm , nor any features due to Polycyclic Aromatic Hydrocarbons (PAHs) at 6.2, 7.7, 8.6 or 11.3 μm (see spectrum in Extended Data Fig. 5). These broadband characteristics suggest that the J160532 disk is settled and evolved, with silicate grains in the disk atmosphere that must have grown to at least 5 μm .

The much higher spectral resolution of MIRI-MRS compared with previous *Spitzer* data reveals numerous narrow hydrogen recombination lines as well as molecular features on top of the continuum (Figure 1). C_2H_2 emission at 13.7 μm is particularly strong, consistent with earlier findings that this molecule is enhanced in disks around brown dwarfs and very low-mass stars^{7, 12, 13}. We focus here on the analysis of the molecular lines and demonstrate that they can be ascribed to a mix of small aliphatic and aromatic hydrocarbon molecules plus CO_2 but that any water lines are weak. Column density ratios are found to be very different from those found in disks around the more massive T Tauri stars.

Figure 1. JWST MIRI-MRS spectrum of J160532 showing prominent C_2H_2 emission. Left: Continuum subtracted MIRI-MRS spectrum of J160532 in the 5–17.5 μm range in black (see also Extended Data Figure 5) compared with a simulated model spectrum of C_2H_2 in red. The two broad continuum bumps at 7.7 and 13.7 μm are reproduced by a high column density, highly optically thick C_2H_2 component I at 525 K with an emitting area of $\pi(0.033\text{au})^2$ which masks the prominent Q -branch at 13.7 μm (see also Extended Data Figure 6). Right: zoom-in on the 13–14.5 μm range, showing that the prominent ν_5 Q -branch of C_2H_2 is well matched by a second, more extended lower column density and less optically thick component II at 400 K with an emitting area of $\pi(0.07\text{au})^2$. The blue line in this zoom-in shows the contribution of the optically thick component I.

Results

Molecular species were identified by matching the most prominent features in the continuum subtracted JWST-MIRI spectrum with synthetic spectra (see Methods section for more details). Most of the bands involve vibration-rotation transitions. The synthetic spectrum of each molecule is calculated from a plane-parallel slab model, where the gas is assumed to have a uniform temperature T and the excitation of the molecules to be in Local Thermodynamic Equilibrium (LTE) at a single excitation temperature T_{ex} equal to T ^{14,15}. The other fitting parameters are the line of sight column density N within a projected emitting area πR^2 given by its radius R . Note that R does not need to correspond to a disk radius, but could also represent a ring with the same area. The best fitting parameters are summarized in Table 1.

The shape and position of any Q -branch, where lines with zero change in rotational quantum number J pile up, are particularly sensitive to temperature. The full ro-vibrational bands of all considered species but H_2O require a treatment of line overlap in the optically thick case. For most species with only a single feature, there is often a degeneracy between a high T , low N optically thin solution and a lower T , high N optically thick case. Uncertainties and degeneracies associated to the fits are evaluated using a χ^2 approach following earlier studies^{14,15} (see Extended Data Figure 7).

– **C_2H_2 and $^{13}\text{C}^{12}\text{CH}_2$:** The Q -branch of C_2H_2 at 13.7 μm associated with the ν_5 bending mode on top of the broad continuum is the most prominent feature in the entire MIRI-MRS spectrum (Figure 1). At $R \sim 3000$, MIRI-MRS also reveals a series of P - and R -branches on top of both the 13.7 μm and 7.7 μm broad bumps. The fact that these bumps coincide in location with emission from gaseous C_2H_2 suggests that the carrier may be due to hot and very abundant C_2H_2 itself. No solid material can be identified that coincides with these broad bumps, and the spacing between the features is too broad to be due to silicate absorption in a near edge-on system suggested based on *Spitzer* data⁷. We demonstrate here that both the broad and narrow components are well reproduced by a two-component model consisting of highly optically thick and more optically thin C_2H_2 emission.

Figure 1 shows that the overall shape of the 13.7 μm continuum bump can be well fit by a slab of gas at

$T = 525$ K with a column density of $N(\text{C}_2\text{H}_2) = 2.4 \times 10^{20} \text{ cm}^{-2}$ within an emitting area of $\pi(0.033 \text{ au})^2$ (i.e., $R = 0.033 \text{ au}$). Our fit includes the contribution of $^{13}\text{C}^{12}\text{CH}_2$, assuming a $\text{C}_2\text{H}_2/^{13}\text{C}^{12}\text{CH}_2$ ratio of 35¹⁶. In the following, this highly optically thick and compact component is called component I. Such an exceptionally high column density of C_2H_2 is required to fully saturate the blended molecular lines and produce a pseudo-continuum that masks any prominent features like the Q -branch (see Extended Data Figure 6). Some fraction of the $7.7 \mu\text{m}$ combination $\nu_4 + \nu_5$ band is also recovered, but with a too high contrast between the amplitude of the narrow features and the level of the pseudo-continuum. At such high column densities, hot bands of $^{13}\text{C}^{12}\text{CH}_2$ that are not included in spectroscopic databases such as HITRAN should contribute significantly as well to the $7.7 \mu\text{m}$ bump and result in a blending of the individual lines. Proper modeling must await more complete $^{13}\text{C}^{12}\text{CH}_2$ molecular spectroscopy including highly excited bands.

The presence of a prominent Q -branch at $13.7 \mu\text{m}$ indicates a second physical component, called component II, producing less optically thick C_2H_2 emission. Our MIRI-MRS data allow to distinguish also the shortward peaks at $13.63 \mu\text{m}$ and $13.68 \mu\text{m}$ due to hot bands that were blended with the main peak in lower resolution *Spitzer* spectra^{7,13} (see Figure 1, right). These features are not tracing the bulk reservoir of C_2H_2 but can either unveil the hotter layer at the surface of the thick component or a more radially extended emission. As an illustration, these features are indeed well reproduced by a somewhat more extended lower column density of $N(\text{C}_2\text{H}_2) = 2.5 \times 10^{17} \text{ cm}^{-2}$ with $R = 0.07 \text{ au}$ at a temperature of 400 K. This component would then trace a physically distinct region, at the outer boundary of the C_2H_2 -rich region of the disk. This is the assumption that we make for the analysis of most of the other molecules, which allows us to subtract the contribution of the two C_2H_2 bumps in the spectra (see Methods section and Extended Data Figure 5) and fit their features without taking into account the masking of the features by optically thick C_2H_2 lines from component I.

The Q -branch of $^{13}\text{C}^{12}\text{CH}_2$ is also detected at $13.73 \mu\text{m}$ above the optically thick component I. If this emission would originate from the optically thinner component II, a $\text{C}_2\text{H}_2/^{13}\text{C}^{12}\text{CH}_2$ abundance ratio of about 3 would be required to match the peak intensity, a value that is an order of magnitude lower than the interstellar $^{12}\text{C}/^{13}\text{C}$ ratio. More likely, this indicates a more complex layered structure than the slab model can simulate. Sophisticated models including radial and vertical gradients of temperature and a more complete spectroscopy of $^{13}\text{C}^{12}\text{CH}_2$ are needed to consistently interpret the prominent peaks of C_2H_2 and $^{13}\text{C}^{12}\text{CH}_2$.

– **C_4H_2** : The emission features at $15.92 \mu\text{m}$ highlighted in Figure 2 correspond to the Q -branch of the fundamental bending mode ν_8 of di-acetylene, C_4H_2 . As for other molecules, the shape of this feature depends strongly on temperature, becoming broader at higher T . Interestingly, an origin within a small emitting area of $R \lesssim 0.07 \text{ au}$ is excluded as line overlap would mask the prominent features. This supports the scenario that the C_4H_2 features originate from the optically thinner component II. This also motivates the choice of our reference emitting area for the thin component to $R = 0.07 \text{ au}$. A model with $T = 330$ K is able to reproduce the feature at $15.92 \mu\text{m}$ as well as that at $15.88 \mu\text{m}$. Moreover, the two emission features between 15.7 – $15.8 \mu\text{m}$ are well reproduced.

– **C_6H_6** : We identified three features around $14.85 \mu\text{m}$ to be the Q -branches of the fundamental and hot bending mode ν_4 of benzene, C_6H_6 , presented in Figure 2. Their relative intensity is sensitive to temperature and indicates $T \simeq 400$ K. As for C_4H_2 , compact emission ($R \lesssim 0.05 \text{ au}$) is excluded.

– **CH_4** : Extended Data Figure 8 shows possible indications of CH_4 emission. CH_4 was previously seen in the GV Tau N disk¹⁷, but only in absorption. We observe emission lines at 7.65 – $7.67 \mu\text{m}$ that are aligned with the Q branch of the ν_4 mode of CH_4 . C_2H_2 also has many emission lines in this region, but cannot reproduce by itself this broad feature.

Figure 2. Detection of C_6H_6 (benzene), CO_2 , and C_4H_2 . Continuum subtracted MIRI spectrum, showing a zoom-in on a number of key molecular transitions in the 14.7–16 μm region (top panel) and their best fit slab models assuming an emitting area of $\pi(0.07\text{au})^2$ (bottom panel). The contribution of the two C_2H_2 bumps (component I) has been subtracted (see Extended Data Figure 5). However, narrow C_2H_2 features are still present shortward of $\approx 15.5 \mu\text{m}$ as exemplified by a slab model of C_2H_2 (green spectrum). We note that CO_2 emission likely originates from the C_2H_2 thick component I with a smaller emitting area of $\pi(0.033\text{au})^2$ (see alternative fit in Table 1).

- **HCN:** The ro-vibrational band from the fundamental ν_2 bending mode of HCN is severely blended with the strong emission lines of C_2H_2 . Extended Data Figure 9 shows the maximum amount of HCN that could be present in the optically thinner C_2H_2 component II. If present in the C_2H_2 thick component I, HCN emission features would be severely masked and its column density in that region cannot be robustly constrained.
- **CO_2 :** Figure 2 includes the fit to the CO_2 bending mode at 14.98 μm that is clearly detected. Assuming that CO_2 emission originates from the C_2H_2 thin component II, the shape of its Q -branch indicates a high temperature around 650 K. Interestingly, the χ^2 fit points also toward a smaller emitting area very close to that for the optically thick C_2H_2 component I with similar temperature and a column density as high as $2 \times 10^{18} \text{ cm}^{-2}$. In the latter case, C_2H_2 can partially mask CO_2 emission but we checked that the fitted column density is then underestimated by less than a factor of 2. The Q -branch of $^{13}\text{CO}_2$ at 15.4 μm is not detected, in line with the column densities reported in Table 1.
- **H_2O :** Extended Data Figure 10 presents blow-ups of the regions of the MIRI spectrum where water can be observed: at 6 μm through the ν_2 ro-vibrational lines, and at $>10 \mu\text{m}$ through highly excited pure rotational transitions^{15, 18}. In the J160532 spectrum, neither set of lines are clearly seen but there are a few weak features around 17 μm that could potentially be consistent with water emission. In those spectral regions, C_2H_2 cannot mask H_2O emission. The values listed in Table 1 could also be viewed as an upper limit on the amount of water hidden in this spectrum. No OH lines are found.
- **H_2 :** Several H_2 pure rotational lines are clearly seen in the MIRI-MRS spectrum, which will be analyzed in detail elsewhere. For a temperature of $\sim 550 \text{ K}$, indicated by the $S(1)/S(3)$ line ratio, the total mass of warm H_2 is about $3 \times 10^{-5} M_{\text{Jup}}$.
- **Other species:** At the shortest MIRI wavelength range, between 4.9 and 5.1 μm , several $\text{CO } \nu = 1 - 0$ P -branch lines are found, indicative of high temperature gas ($T > 1000 \text{ K}$) that will be analyzed elsewhere. Several other hydrocarbon species (C_2H_4 , HC_3N) were searched for in the J160532 spectrum, but not identified. Also, NH_3 , whose ν_6 mode at 8.8 μm can be observed with MIRI, was not found in the current spectrum. The [Ne II] line at 12.8 μm is not detected.

Table 1. Best fit slab model results for molecules in the J160532 disk.

Molecule	Component I ^a		Component II	
	<i>T</i> (K)	<i>N</i> (10 ¹⁷ cm ⁻²)	<i>T</i> (K)	<i>N</i> (10 ¹⁷ cm ⁻²)
C ₂ H ₂	525	2400 ⁺³²⁰⁰ ₋₁₄₀₀	400	2.5
C ₄ H ₂	-	-	330	0.7
C ₆ H ₆	-	-	400	0.7
CH ₄	-	-	400 ^b	1.5
CO ₂	430	20 ⁺⁵⁵ ₋₁₈	650	0.36
HCN	-	-	400 ^b	≤ 1.5
H ₂ O	525 ^b	≤ 30	400 ^b	≤ 8

Note a: for H₂O and CO₂, the reported values correspond to an alternative fit to component II assuming that all the emission originates from the C₂H₂ thick component I ($R = 0.033$ au).

Note b: fit performed by fixing the temperature to that of the corresponding C₂H₂ component.

Uncertainties on the column densities correspond to the 1 σ confidence interval obtained by fixing the emitting area and are only valid in the framework of our simple slab modelling. For clarity, uncertainties smaller than 0.5 dex are not reported.

Discussion

The most striking feature of the J160532 MIRI spectrum is the dominance of hydrocarbon emission, most notably C₂H₂, but also C₄H₂, C₆H₆ (benzene), and possibly CH₄. In contrast, at best weak H₂O emission is found, and CO₂ has a similar column density as most hydrocarbons in component II (Table 1). Hydrocarbon molecules like C₄H₂ and benzene have been found previously in some astrophysical environments, including asymptotic giant branch stars, comets and moons in our own Solar System^{19–21}, but not yet in the planet-forming zones of disks. These detections therefore highlight that the inner disks around very low-mass objects are indeed very rich in carbon-bearing molecules as suggested based on *Spitzer* data^{7,12,13}. The high column densities point toward being able to probe deep down layers, likely due to a lack of grains in the inner disk.

Figure 3 summarizes the observed column density ratios of key molecules in J160532 with those found in disks around more massive T Tauri stars¹⁵. For the latter, the sources listed in Table 8 of Salyk et al.¹⁵ with detected C₂H₂ and H₂O are taken. The C₂H₂/H₂O ratio for the optically thick component I is up to 5 orders of magnitude higher in the J160532 disk than for T Tauri disks, and even more if H₂O is treated as an upper limit. Similarly, the C₂H₂/CO₂ ratio is 2 orders of magnitude higher. These ratios are much higher than just the flux ratios shown in Extended Data Figure 11 since our analysis, including the hot bands and a detailed treatment of line overlap, clearly demonstrates that the C₂H₂ emission is highly optically thick boosting its column density by orders of magnitude. Note that these column density ratios should not be viewed as local abundance ratios since each molecular band may originate from a different part of the disk, with abundances known to vary radially and vertically²².

Nevertheless, the J160532 disk is clearly rich in hydrocarbon molecules and the observed chemical differences indicate that hydrocarbon molecules either form more efficiently in disks around very low-mass stars, or that the conditions for their survival are more favorable there. One difference is the UV spectrum

of the central star, which has many fewer high energy photons that can photodissociate molecules for an M-type star than for an early K- or G-type star. However, J160532 still does have some accretion consistent with its relatively young age of 2.5 Myr; its estimated FUV luminosity of $\log(L_{\text{FUV}}) = -3.59 L_{\odot}$ ⁷ is comparable to that of T Tauri stars. As an M star, J160532 may also have chromospheric activity and flares producing enhanced UV and X-rays, the latter estimated⁷ at $\log(L_X) = 28.8 \text{ erg s}^{-1}$.

The alternative possibility is enhanced C_2H_2 production. Carbonaceous grains and PAHs can be destroyed in the inner disk due to UV radiation, chemical processes or sublimation producing abundant C_2H_2 ^{23,24}. Interestingly, the so-called hydrocarbon “soot” line as defined by the sublimation front of refractory carbon is estimated to lie at 500 K²⁵, the temperature found for the abundant optically thick C_2H_2 component I. The exact location of the “soot” line is however uncertain and depends on the type of carbonaceous material, with some laboratory data putting sublimation of amorphous carbon grains at higher temperatures, up to 1200 K²⁶. One possibility is therefore that we are witnessing carbon grain destruction in the inner disk. Is carbon grain destruction observable in other disks? This remains an open question to be tackled with the upcoming JWST data. If carbon grains are destroyed by UV photolysis, it could be dramatically enhanced in J160532 due to dust growth and settling which increase the penetration depth of the UV. Alternatively, carbon grain destruction could be happening primarily in the high temperature midplane that is uniquely visible in the J160532 disk but hidden from our view in most disks due to the presence of dust with high infrared optical depth.

Figure 3. Column density ratios in the inner disk of J160532. Comparison of the observed column density ratios in component I with an emitting area of $\pi(0.033 \text{ au})^2$ in the disk of J160532 with those found for T Tauri disks with detected C_2H_2 and H_2O ¹⁵. The ratios are also compared with those found in thermo-chemical disk models that assume solar C/O elemental ratios¹⁶. Note that column density ratios should not be equated with abundance ratios since abundances of individual molecules vary strongly radially and vertically. The error bars on the measured J160532 ratios are 1σ confidence interval estimated from our χ^2 fit assuming similar emitting areas for CO_2 and C_2H_2 . The error bars on the ratios measured in the T Tauri sample correspond to the $\pm 1\sigma$ of the distribution.

Further insight into the hydrocarbon chemistry can be obtained from comparison of our observed column density ratios with those found in thermo-chemical models²⁷ of disks around low-mass stars (see Methods section for more details). Interestingly, both benzene and C_4H_2 were predicted to be abundant in inner disk regions^{16,28}. For the optically thin C_2H_2 component II in which these molecules are not

masked by optically thick C_2H_2 , we find relatively good agreement with the models even though benzene is underestimated by the models (see Extended Data Table 2). Under these conditions – warm dense gas with high C_2H_2 abundance – one would expect also efficient PAH formation up to temperatures where erosion starts to take over^{29,30}. To what extent the absence of PAH features in the J160532 spectrum also implies absence of PAHs, or whether there is simply not enough UV radiation to excite and make them visible³¹, needs to be quantified. A detailed comparison using a physical-chemical model appropriate for the J160532 disk is postponed to a future study.

An additional source of C_2H_2 production due to carbon grain destruction in the J160532 disk would also be consistent with the fact that the observed $\text{C}_2\text{H}_2/\text{H}_2\text{O}$ ratio is four orders of magnitude higher than what is found in those models. CO_2 is underabundant as well by two orders of magnitude. This conclusion holds irrespective of the stellar mass and adopted UV field in the models²⁷.

Najita et al.^{32,33} suggested that the range in observed $\text{HCN}/\text{H}_2\text{O}$ ratios for T Tauri stars implies different C/O ratios in the inner disk. High $\text{HCN}/\text{H}_2\text{O}$ ratios would indicate that H_2O is locked up in non-migrating pebbles and planetesimals in the outer disk beyond the water iceline. In the J160532 disk, the $\text{HCN}/\text{H}_2\text{O}$ ratio cannot be robustly constrained but the $\text{C}_2\text{H}_2/\text{H}_2\text{O}$ ratio is much higher than for T Tauri disks.³⁴ In fact, thermochemical disk models of cool M-type stars predict a low H_2O abundance due to the lower temperature of their disks driving much of the oxygen into O_2 ²⁷. Still, for solar C/O ratios, CO_2 is predicted to be one of the main oxygen carriers after CO and O_2 , in stark contrast with our estimates of the $\text{CO}_2/\text{C}_2\text{H}_2$ ratio. Such high abundance ratios as found here can therefore only be reproduced if the C/O ratio of the gas in the inner disk is significantly increased compared with standard values of $\text{C}/\text{O}=0.4$ ⁷. In fact, the models of Najita et al.³², Woitke et al.²² and Anderson et al.³⁵ show that values of $\text{C}/\text{O} \gtrsim 1$ are needed to ensure that the bulk of the volatile oxygen is contained in CO leaving little room for H_2O and CO_2 production, and permitting the formation of abundant C_2H_2 .

What could cause the inner disk to be depleted in oxygen compared to carbon? Destruction of carbon-rich grains helps to boost carbon and thus the gas-phase C/O ratio by about a factor of 2 compared to the volatile carbon in the interstellar medium (about 50% of the total elemental carbon), enough to put the C/O ratio close to unity. However, the very high C/O ratio inferred for the inner disk of J160532 may also point toward a depletion of oxygen. To deplete the inner disk of oxygen the most plausible mechanism would be to lock most of it up in water ice in pebbles and planetesimals in the outer disk, beyond the water snowline, which for such a low mass star is around 0.1 au³⁶. Gas with high C/O, as often found in the outer disk³⁷, could still be able to cross the gap. Little is known about the small scale structure of disks around very low mass stars like J160532, but our findings would imply that such dust disks are not smooth but must have significant substructure with dust and ice traps on (sub)au scales^{38,39}, as illustrated in Figure 4. To avoid much oxygen crossing these traps, they must develop early in the disk’s evolution, perhaps due to a companion that has formed there. ALMA observations of the outer disk, and analysis of H_2 and ro-vibrational CO emission from the inner disk, combined with detailed modelling, are required to constrain the gas-phase C/O and O/H elemental ratios in the inner versus outer disk and further quantify the destruction of carbon grains and the efficiency of oxygen trapping in the outer disk.

What are the implications for any planets forming around J160532? The current amount of solid material contained in millimeter-sized grains in its disk after 2.5 Myr of evolution is less than an Earth mass⁸, but the system could have started forming planetesimals and building planets earlier in its lifetime. In fact, there is ample evidence for efficient terrestrial planet formation around very low-mass objects. The occurrence rate per M-dwarf is 2.5 ± 0.2 planets with radii of 1–4 R_{Earth} and periods < 200 days¹. Surveys also find that short-period (< 10 days) planets around stars with $M_* < 0.34 M_{\odot}$ are significantly overabundant relative to more massive stars². Our JWST data reveal that the chemistry in disks around such very low-mass stars may have an even higher gaseous C/O ratio in the planet-forming zones than

Figure 4. The possible structure of the inner part of the J160532 disk. This illustration shows the silicate dust sublimation radius around 0.01 au, the destruction front of carbonaceous grains around 0.033 au (either by sublimation, UV photolysis, or chemical processes), and the water snowline around 0.1 au. In this schematic view, the outer radius of the optically thick C_2H_2 component I is put at 0.033 au derived from the fitted emitting area of $\pi(0.033 \text{ au})^2$. The location of the silicate and water sublimation fronts is estimated from the luminosity of the star. The top shows the high C/O ratio in the gas in the very inner disk and the low C/O ratio in icy grains at larger radius. The inner disk contains only large ($> 5 \mu\text{m}$) silicate grains. The location of any dust trap locking up water ice is unconstrained, except that it must be outside the water snowline at ~ 0.1 au. Note the log scale for the distance to the star.

thought before. This, in turn, could significantly affect the composition of planets that may form around them.

To what extent the planets inside 0.1 au are also carbon rich will depend on whether they are formed mostly from “dry” planetesimals in this inner disk, or whether their bulk composition and atmospheres result primarily from impacting icy planetesimals from the outer disk, as found in scenarios for making terrestrial planets^{40,41}. In fact, it is not clear whether planetesimals formed in the inner disk are carbon rich: our data indicate the presence of some warm silicate refractory dust producing continuum mid-infrared emission, whereas a significant fraction of the carbon may be in the gas-phase and even refractory carbon grains may have been destroyed. This carbon-rich gas could be lost from the system over time, with only a small fraction of carbon eventually included in planets⁴². Such a scenario likely holds for our own Earth which is known to be very carbon poor²⁵. These two competing scenarios — making carbon-rich versus carbon-poor terrestrial planets — can be tested by comparing high sensitivity JWST observations of the chemical composition of significant samples of disks around very low-mass young stars with that of the atmospheres of terrestrial-sized planets around mature M stars like the Trappist I system⁴³ and brown dwarfs.

Methods

Observations and data reduction

J160532 was observed with the JWST Mid-InfraRed Instrument (MIRI)^{9,44,45} in Medium Resolution Spectroscopy mode (MRS)⁴⁶ on 2022 August 1, from 05:50:01 UT, for a total observation time of 2.22 hours. The observation is number 47 of the Cycle 1 Guaranteed Time Observation (GTO) program 1282 (PI: Thomas Henning). Following target acquisition, the three grating settings Short (A), Medium (B) and Long (C) were used in each of the four channels observations carried out in parallel, providing full coverage of the MIRI spectral window 4.9 – 28.1 μm . For each of the three sub-bands, the FASTR1

readout pattern was adopted with a point source 4-point dither pattern, an exposure time of 308 s and an integration time of 74.9 s.

For the reduction of the uncalibrated raw data, we used the version 1.8.4 of the JWST Science Calibration Pipeline⁴⁷ and the CRDS context `jwst_1017.pmap`. The uncal files were first processed with the default class of the pipeline `Detector1`. Next, we performed a background correction by subtracting each dither pattern from the other associated pattern (1 from 4, 2 from 3 and vice-versa). We then applied the default class `Spec2`, skipping the residual fringe correction. The data were then processed by the `Spec3` class, which combines the calibrated data from the different dither observations into a final level3 spectral cube. We skipped the `outlier_detection` and `master_background` methods of the class, since we already performed the background subtraction after `Detector1`. We set `Spec3` to produce one spectral cube for each sub-band, from which we extracted the spectrum using the pipeline method `extract1d`. This was done in order to provide the best input for a residual fringe correction that we applied at the spectrum level.

Local continuum fit

Extended Data Figure 5 shows the baseline fit used to produce the spectrum in Figures 1 and 2. Starting from the original spectrum, first a low-order continuum due to warm dust emission has been removed over the entire 5-20 μm range, producing Figure 1. Subsequently, the two broad bumps at 7.7 μm and 13.7 μm have been subtracted in Figures 2, 8, and 10 to further analyse all the molecular features except that of the very optically thick bumps of C_2H_2 (component I).

Slab model fits

The molecular lines are analysed using a slab approach that takes into account optical depth effects. The level populations are assumed to be in local thermodynamical equilibrium (LTE) and the line profile function to be Gaussian with an intrinsic broadening of $\sigma = 2 \text{ km s}^{-1}$ (FWHM of $\Delta V = 4.7 \text{ km s}^{-1}$) to include the effect of turbulence. We note that for optically thin lines, the inferred column densities are independent of the value of ΔV whereas for optically thick emission, the inferred column densities scale approximatively as $1/\Delta V$. The line emission is assumed to originate from a layer of gas with a temperature T and a line of sight column density of N . Because most of the species analysed here produce lines that are close to each other in frequency, we adopt a detailed treatment of line overlap by first computing the wavelength dependent opacity over a fine grid of wavelength ($\lambda/\Delta\lambda \simeq 10^6$)

$$\tau(\lambda) = \sum_i \tau_{0,i} e^{-(\lambda - \lambda_{0,i})^2 / 2\sigma_\lambda^2}, \quad (1)$$

where i is the line index, $\lambda_{0,i}$ is the rest wavelength of line i , σ_λ is the intrinsic broadening of the line in μm , and $\tau_{0,i}$ is the optical depth at the center of line i given by

$$\tau_0 = \sqrt{\frac{\ln 2}{\pi}} \frac{A_{ul} N \lambda_0^3}{4\pi \Delta V} \left(x_l \frac{g_u}{g_l} - x_u \right). \quad (2)$$

In this equation, x_u and x_l denote the population level of the upper and lower states, g_u and g_l their respective statistical weights, and A_{ul} the spontaneous downward rate of the transition. The flux density $F(\lambda)$ is then computed assuming an emitting area of πR^2 and a distance to the source d as:

$$F(\lambda) = \pi \left(\frac{R}{d} \right)^2 B_\nu(T) (1 - e^{-\tau(\lambda)}), \quad (3)$$

and convolved at MIRI-MRS spectral resolution. This special treatment, though computationally expensive, is particularly crucial at high column densities for which overlapping lines can form an effectively

optically thick continuum across a relatively broad spectral range (see Extended Data Figure 6). Our code has been benchmarked against the publicly available code `slabspec`⁴⁸.

The molecular data, i.e., line positions, Einstein A coefficients, statistical weights, and partition functions, were taken from the HITRAN 2020 database⁴⁹, except for C_6H_6 for which the molecular parameters were provided based on the GEISA database⁵⁰. We provide further details about the C_6H_6 line list used in the next section.

Protoplanetary disks are obviously not isothermal (vertically or radially), but previous studies have shown that the LTE assumption is a good first step approximation to determine the relative column densities of molecules and physical parameters of the line-emitting regions^{14,15}. Non-LTE effects can play a role for the higher excited energy levels⁵¹ if the local density is less than $\sim 10^{15} \text{ cm}^{-3}$. Differences up to factors of 3 in inferred column densities have been found in LTE vs non-LTE comparisons for the case of HCN ro-vibrational lines⁵². Since non-LTE effects are expected to be comparable and in the same direction for different molecules, the effect on column density ratios is expected to be smaller than such a factor of 3.

Given the overwhelming presence of the C_2H_2 band in the MIRI spectrum, we first fit the broad continuum bump (component I) between 12 and 17 μm using a χ^2 approach (see Extended Data Figure 7, left) and including the contribution of $^{13}C^{12}CH_2$ with a $C_2H_2/^{13}C^{12}CH_2$ ratio of 35, half of the interstellar medium value to account for two carbon atoms¹⁶. In order to avoid the contribution of the other molecular features, the χ^2 fit is computed using 4 spectral windows (12.1 – 12.2 μm , 12.65 – 12.9 μm , 14.6 – 14.85 μm , and 15.5 – 15.7 μm). We then find a more optically thin model that reproduces well the main Q -branches of C_2H_2 and $^{13}C^{12}CH_2$, assuming that this second component II originates from a different region of the disk. This model, with an emitting area corresponding to $R = 0.07 \text{ au}$, is only illustrative since the accuracy of this fit is limited by the lack of spectroscopic data of $^{13}C^{12}CH_2$. Excited states of the ν_5 band of $^{13}C^{12}CH_2$ are indeed missing in the molecular databases whereas the contribution of those states to the Q -branch of C_2H_2 is expected to be significant.

The resulting C_2H_2 models for both component I and II are then subsequently used in the analysis of the other species to identify spectral windows that are free of contamination by narrow C_2H_2 features (see e.g., Extended Data Figure 8). However, in order to subtract the contribution of optically thick C_2H_2 (component I), we do not use the best fit model but subtract a spline fit through the two broad C_2H_2 bumps. This strategy avoids artefacts in the subtracted spectra that would be due to the imperfect C_2H_2 model.

When subtracting the prominent C_2H_2 bumps prior to the fit of the other features, we implicitly neglect mutual line overlap between C_2H_2 and the other species which can be relevant if the emission of the species originates from the optically thick C_2H_2 component I. In fact, as discussed in the main text, only the analyses of CO_2 and HCN are affected by C_2H_2 opacity. This is because CO_2 and HCN features could originate from component I and are located close to prominent C_2H_2 lines. For HCN, masking by C_2H_2 is too significant to put constraints on the amount of HCN in component I. For CO_2 , we conducted additional tests and find that the derived column densities of CO_2 for component I change by only a factor of less than two when including mutual shielding of the lines.

The best fit slab model parameters (N , T , emitting area characterized by R) for the species other than C_2H_2 are then estimated by a χ^2 approach (see Extended Data Figure 7). Extensive grids of models varying the column density from 10^{15} up to 10^{22} cm^{-2} , in steps of 1.26 in $\log_{10}$ -space and temperature from 100 up to 1500 K in steps of 25 K were computed. Given that C_2H_2 emission is highly optically thick, the fit of the 13.7 μm bump allows us to determine the emitting radius of $R = 0.033 \text{ au}$. Interestingly, the fit of the CO_2 feature points toward a similarly small emitting area. In contrast, for the C_4H_2 and benzene prominent features, a compact emission with $R \lesssim 0.07 \text{ au}$ is excluded. When the χ^2 cannot constrain the

emitting size (optically thin lines), the same emitting radius of 0.07 au is used to evaluate or place upper limits on column densities (CH_4 , C_6H_6 , C_4H_2 , HCN). For H_2O , the emitting area is unconstrained and we provide (upper limit) column densities for either component I or II in Table 1.

In the calculation of the χ^2 , specific spectral windows are chosen to avoid contamination by other molecular features. The 1, 2, and 3 σ confidence intervals are estimated by drawing the contours of $\Delta\chi^2_{\text{red}} = \chi^2_{\text{red}}(N, T) - \chi^2_{\text{red}, \text{min}}$ corresponding to values of 2.3, 6.2, and 11.8, respectively, and using a representative noise level of $\sigma = 0.14$ mJy, where $\chi^2_{\text{red}}(N, T)$ is the reduced χ^2 obtained by fitting the emitting area for a given value of (N, T) [53, see e.g.,].

Benzene spectroscopy

Benzene is included in the GEISA database⁵⁰, but the existing line list does not provide Einstein A coefficients nor statistical weights and involves only the cold ν_4 band centered at $14.837 \mu\text{m}$ (673.975 cm^{-1}). Therefore, the missing spectroscopic parameters that are necessary for the present study have been generated.

For the cold ν_4 band, we completed the line list, in terms of nuclear spin statistical weights and Einstein coefficients, using the method described in ref.⁵⁴, and the available spectroscopic constants⁵⁵. For the partition function, that involves a vibrational and a rotational contribution, we used the empirical equations of ref.⁵⁵. Before this, we made extensive calculations to check that these equations are usable for the $50 \text{ K} < T < 500 \text{ K}$ temperature range with an error that is less than 0.5%. The contribution of hot bands at $14.9 \mu\text{m}$ is missing in the GEISA line list. For this heavy molecule, these hot bands contribute about 45 % to the infrared activity at $14.9 \mu\text{m}$ at room temperature. To account for these contributions, we generated empirical line lists, using the cold ν_4 band as a “guide list” and the cross-section measurements of benzene performed at high resolution and for different temperatures⁵⁶.

Details of disk models

The observational results are compared with a number of state-of-the-art thermochemical disk models in Extended Data Table 2. In this comparison, we show two observational values of the ratios; assuming either an emitting region corresponding to the highly optically thick component I of C_2H_2 , or from the less optically thick component II. The thermochemical models assume a gas surface density structure, often taken to be the self-similar solution of a viscously evolving disk. Since we are only interested in the inner few au of the disk, the precise shape and size of the outer disk are not relevant. The gas distribution in the vertical direction is characterized by a scale height and flaring index. The disk is irradiated by the star whose FUV spectrum is given by its effective temperature T_{eff} and strength by its luminosity. Extra UV due to accretion is modelled by adding a 10^4 K black body with a strength proportional to the observed accretion rate or L_{FUV} . X-rays and cosmic rays are also included, the latter usually at a generic rate of $\sim 10^{-17} \text{ s}^{-1}$.

The models first solve for the dust temperature given the source’s luminosity, and then either assume that the gas temperature is equal to the dust temperature or solve explicitly for the gas temperature by iterating over the heating and cooling balance with a small chemical network. Typical gas temperatures in the inner ($< 1 \text{ au}$) disk are a few thousand K at the top of the atmosphere, dropping to several hundred K deeper in the disk where most of the molecular emission originates²². Such temperatures are consistent with our inferred values of 300–600 K for C_2H_2 and other molecules. Finally, the 2D abundance distribution of each molecule can be determined by solving the chemistry at each grid point using a more extensive chemical network. Details can be found in refs.^{22,32,57}.

Most relevant for comparison with our observations are those models that include a large hydrocarbon network. In particular, Woods & Willacy¹⁶ have developed a detailed chemical model appropriate for a disk around a T Tauri star including not just ^{12}C but also ^{13}C isotopologues. We take the column densities

at 1 au from their Table 3 for comparison in Figure 3. Walsh et al.²⁷ have run chemical models for disks around a M dwarf, a T Tauri star and a Herbig star, to investigate how the chemistry differs across the stellar mass range. We focus here on their results for the M-dwarf disk. Walsh et al. show not only total column densities as function of disk radius, but also the column densities above the dust $\tau = 1$ surface at $14\ \mu\text{m}$, since mid-infrared observations do not probe down to the midplane. We take the latter for our comparison. None of these models vary the input volatile C and O abundances (i.e., the amount of carbon and oxygen that can cycle between gas and ice), which are usually taken such that oxygen is more abundant than carbon at C/O=0.4.

Najita et al.³² have also presented sophisticated inner disk models focusing on smaller molecules up to C_2H_2 , HCN and H_2O to investigate trends with disk parameters and C/O. Their models include accretional heating and stellar X-rays, but not FUV radiation in the heating and chemistry. Their model abundances of hydrocarbon molecules are clearly increased when C/O is increased. The same is found in more recent models by Woike et al.²² and Anderson et al.³⁵.

1 Extended Data

Extended Data Figure 5. Comparison between the *Spitzer*-IRS spectrum and the MIRI-MRS spectrum and baseline fits of the MIRI-MRS spectrum. The *Spitzer*-IRS low-resolution spectrum⁵⁸ has been shifted by 5 mJy to ease the comparison with the MIRI-MRS spectrum (top panel). Baseline fits used in the continuum subtracted spectrum presented in Figure 1 and 2 in the Results section are shown in the middle and bottom panel, respectively. The blue dots represent the location where the continuum is evaluated. The red curve is the interpolated continuum used to produce continuum-subtracted spectra (in grey). The presence of warm dust is evidenced by the infrared continuum emission on either sides of the two C_2H_2 bumps but no silicate feature is detected. HI and H_2 lines are present in the spectrum and will be analysed in a next paper.

Extended Data Figure 6. Effect of line overlap on the main C_2H_2 feature at $13.7\ \mu\text{m}$. *Left:* C_2H_2 emission as function of column density for $T = 500\ \text{K}$ and $R = 0.1\ \text{au}$. Note that the Q -branch becomes highly optically thick above $N(\text{C}_2\text{H}_2) = 10^{20}\ \text{cm}^{-2}$ and flattens. The contrast between the amplitude of the narrow features on either side of the Q -branch and the continuum level decreases by increasing $N(\text{C}_2\text{H}_2)$. A column density of at least $N(\text{C}_2\text{H}_2) \simeq 10^{20}\ \text{cm}^{-2}$ is required to fit the observations. *Right:* Importance of line overlap in slab models. For highly optically thick lines that are close to each other such as in the Q -branch of C_2H_2 , slab models neglecting line-overlap overestimate the fluxes. For C_2H_2 , this effect dominates for $N \gtrsim 10^{19}\ \text{cm}^{-2}$.

Extended Data Figure 7. Constraints obtained from χ^2 fits. The χ^2 maps for the fit of the $13.7\ \mu\text{m}$ broad bump associated with C_2H_2 (left), and the CO_2 (middle) and C_4H_2 (right) features are shown. The 1σ , 2σ , and 3σ confidence intervals are pictured in red, yellow, and orange, respectively. The best-fitting emitting radius R for each value of N and T is indicated as grey lines. In general, we find a degeneracy between a high T and low N solutions, and a low T and high N solutions. For CO_2 the best fit corresponding to an emitting area of $0.033\ \text{au}$ is chosen to alleviate the degeneracy and compare with the optically thick component of C_2H_2 (component I). We note that for $R = 0.07\ \text{au}$, corresponding to component II, the CO_2 feature can be fitted by either a hot and thin model or a cold and thick model. However, the thick solution over-predicts $^{13}\text{CO}_2$ emission which is not detected. We therefore report in Table 1 the column density of the optically thin solution for component II.

Extended Data Figure 8. Possible indication for CH₄ emission in the 7.64-7.77 μm range. CH₄ emission could be present at 7.655 μm in addition to the many C₂H₂ lines in this region. The column density of CH₄ is estimated assuming that the emission originates from component II (see main text, Table 1). The C₂H₂ model in purple corresponds to the component II for which the best-fit column density has been increased by a factor of 4 to better match the series of C₂H₂ lines in that specific spectral region.

Extended Data Figure 9. Constraints of the amount of HCN in the 14 μm region. The C₂H₂ model, including both component I and II is shown in red on top of the MIRI spectrum where the contribution of the C₂H₂ thick component is not subtracted. This figure shows that a maximum column density of HCN of $N = 1.5 \times 10^{17} \text{ cm}^{-2}$ can be hidden in the C₂H₂ line forest in this region assuming an origin in the optically thin component II ($R = 0.07 \text{ au}$ and $T = 400 \text{ K}$). HCN emission from the C₂H₂ thick component I would be highly masked by C₂H₂ and therefore its column density remains unconstrained.

Supplementary Table 2. Observed column density ratios of various species compared with disk models with solar C/O elemental ratio in the gas-phase.

Ratio	Observations ^a		TTauri model	BD model
	Component I	Component II	WW 09 ²	WNvD15 ³
C ₄ H ₂ /C ₂ H ₂	-	0.3	0.18	-
CH ₄ /C ₂ H ₂	-	0.6	0.18	-
C ₆ H ₆ /C ₂ H ₂	-	0.3	0.02 ⁴	-
CO ₂ /C ₂ H ₂	8×10^{-3}	0.14	2.0	-
H ₂ O/C ₂ H ₂	$\leq 1 \times 10^{-2}$	≤ 3	192	100

1. Assuming that the emission is either confined to the C₂H₂ highly optically thick component I or the optically thinner component II. The prominent features of the small hydrocarbons are associated to the extended component II only whereas the CO₂ emission originates more likely from the thick component I (see main text). 2. Woods & Willacy (2009). 3. Walsh, Nomura & van Dishoeck (2015). 4. Woods & Willacy (2007).

Extended Data Figure 10. Possible detection of weak H₂O lines in the 17.2 μm and 6.5 μm regions. The pure rotational lines at 16.5–18 μm can hide as much as $N(\text{H}_2\text{O})=3 \times 10^{18} \text{ cm}^{-2}$ assuming a fixed temperature of 525 K and a characteristic emitting radius of $R = 0.033 \text{ au}$, corresponding to the optically thick C₂H₂ component I. These lines are not affected by masking of C₂H₂ since only very weak lines of C₂H₂ are present in these spectral ranges. Some lines in the 6.3–6.8 μm range are somewhat overestimated by our LTE model but non-LTE effects will tend to quench these lines compared to the pure rotational lines longward of $\sim 12 \mu\text{m}$ ⁵⁹.

Extended Data Figure 11. J160532 line fluxes compared to other disks. This figure presents a comparison of C₂H₂ versus H₂O flux scaled to 140 pc for a number of T Tauri disks observed with *Spitzer* and compiled by ref.⁶⁰ and J160532 observed with JWST MIRI. The line fluxes for J160532 are consistently calculated by integrating the flux of the three water features at 17.12 μm , 17.22 μm , and 17.36 μm , and the C₂H₂ feature over a window between 13.65–13.72 μm as explained in ref.⁶⁰. Leftward (resp. downward) arrows represent upper limits on H₂O (resp. C₂H₂) line flux.

Data Availability

The original data analysed in this work are part of the GTO-MIRI programme "MIRI EC Protoplanetary and Debris Disks Survey" (ID 1282) with number 47 and will become public on August 1 2023 on the MAST database <https://archive.stsci.edu/>. The continuum-subtracted spectra presented in Figure 1 (right) and in Figure 2 will be made available on Zenodo upon publication. The spectroscopic data for all the species but benzene are available on the HITRAN database (<https://hitran.org/>). For benzene, the data will be shared on request to the corresponding author.

Code Availability

The slab model used in this work is a private code developed by BT and collaborators. It is available from the corresponding author upon request. The synthetic spectra presented in this work can be reproduced using the `slabspec` code, which is publicly available at <https://doi.org/10.5281/zenodo.4037306>.

Author contributions

BT and GB did the analysis using molecular data files created by AA and AP and a model developed by BT and JB. GB, SG and DG performed the data reduction, supported by IA, JS, MS, GP, VC, and JB. EvD, BT, and GB wrote the manuscript. TH and IK planned and co-led the MIRI guaranteed time project on disks. All authors participated in either the development and testing of the MIRI instrument and its data reduction, in the discussion of the results, and/or commented on the manuscript.

Competing Interests

The authors declare no competing financial interests.

Correspondence

Correspondence and requests for materials should be addressed to Benoit Tabone, benoit.tabone@universite-paris-saclay.fr.
