## ABSTRACT

The Galactic Archaeology with HERMES (GALAH) survey is a massive observational project to trace the Milky Way’s history of star formation, chemical enrichment, stellar migration and minor mergers. Using high-resolution ( $R \simeq 28\,000$ ) spectra, taken with the High Efficiency and Resolution Multi-Element Spectrograph (HERMES) instrument at the Anglo-Australian Telescope, GALAH will determine stellar parameters and abundances of up to 29 elements for up to one million stars. Selecting targets from a colour-unbiased catalogue built from 2MASS, APASS and UCAC4 data, we expect to observe dwarfs at 0.3–3 kpc and giants at 1–10 kpc. This enables a thorough local chemical inventory of the Galactic thin and thick discs, and also captures smaller samples of the bulge and halo. In this paper, we present the plan, process and progress as of early 2016 for GALAH survey observations. In our first two years of survey observing we have accumulated the largest high-quality spectroscopic data set at this resolution, over 200 000 stars. We also present the first public GALAH data catalogue: stellar parameters ( $T_{\text{eff}}$ ,  $\log(g)$ ,  $[\text{Fe}/\text{H}]$ ,  $[\alpha/\text{Fe}]$ ), radial velocity, distance modulus and reddening for 10 680 observations of 9860 *Tycho-2* stars, 7894 of which are included in the first *Gaia* data release.

**Key words:** stars: abundances – Galaxy: disc – Galaxy: evolution – Galaxy: formation – Galaxy: stellar content.

## 1 INTRODUCTION

Massive observational surveys are an increasingly important force in astronomy. In particular, spectroscopic stellar surveys are revolutionizing our understanding of Galactic structure and evolution (e.g. Helmi 2008; Rix & Bovy 2013; Hayden et al. 2014, 2015; Martig et al. 2016). As in many areas of astronomical research, this development is driven by technology. Efficient methods for accurately positioning many optical fibres at telescope focal planes are enabling an increasing number of observatories to add highly multiplexed high-resolution spectrographs to their instrument suites (e.g. Cui et al. 2012; Sugai et al. 2015).

The Galactic Archaeology with HERMES (GALAH) survey<sup>1</sup> is a high-resolution spectroscopic survey that is exploring the chemical and dynamical history of the Milky Way, with particular focus on the disc. GALAH aims to collect a comprehensive data set, in terms of both sample size and detail, with abundances for as many as 29 elements (Li, C, O, Na, Mg, Al, Si, K, Ca, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Rb, Sr, Y, Zr, Ru, Ba, La, Ce, Nd, Eu) for each target. Our overall science goal is to carry out chemical tagging (e.g. Freeman & Bland-Hawthorn 2002; De Silva et al. 2006; Bland-Hawthorn et al. 2010b) within this data set, identifying stars that formed at the same time and place by matching their abundance patterns. A thorough explanation of the GALAH survey science goals is given in De Silva et al. (2015).

<sup>1</sup> <http://galah-survey.org>

The project of chemical tagging in the Galactic disc demands a very large data set. Given the observational selection for GALAH targets (discussed in Section 3 below), we anticipate that roughly 75 percent of stars observed by GALAH will belong to the thin disc and 24 percent to the thick disc, with smaller numbers of nearby halo stars and bright red giants in the bulge making up the rest of the sample. From theoretical explorations of clustered star formation (e.g. Bland-Hawthorn, Krumholz & Freeman 2010a; Feng & Krumholz 2014), we expect there to be stars from a large number of unique star-forming events (‘initial star-forming groups’) mixed throughout both the thin and thick discs. The number of these groups in the disc, and the number of stars per group, will depend on the initial mass function and maximum mass of each group. Ting, Conroy & Goodman (2015) predicted that a survey of  $10^5$  stars can expect to observe 10 stars per group down to an initial mass limit of  $\sim 10^6 M_{\odot}$ , while a survey of  $10^6$  stars would capture 10 stars per group down to a group mass of  $\sim 10^5 M_{\odot}$ . Ting, Conroy & Rix (2016) took data for 13 000 stars from the Apache Point Observatory Galaxy Evolution Experiment (APOGEE; Holtzman et al. 2015; Majewski et al. 2015) survey from the twelfth data release of the Sloan Digital Sky Survey (SDSS DR12; Alam et al. 2015). By analysing the ‘clumpiness’ of the chemical abundance data rather than carrying out strict chemical tagging, they were able to rule out the presence of an initial star-forming group in the thick disc with a mass greater than  $10^7 M_{\odot}$ .

Our observational programme must therefore collect enough stars from each initial star-forming group, and derive precise enough stellar parameters and elemental abundances, to confidently apply chemical tags to them. Since the observing time for GALAH is allocated through the competitive time-allocation process of the 3.9 m Anglo-Australian Telescope (AAT), our observing strategy must provide this large, high-quality sample in a reasonable amount of observing time. This paper describes the balance between sample size, signal-to-noise ratio (SNR) and observing time, which has been designed into our observational programme. Section 2 outlines the capabilities of the High Efficiency and Resolution Multi-Element Spectrograph (HERMES) and Two Degree Field (2dF) fibre positioner; Section 3 discusses our target selection for the main survey; Section 4 describes the observing procedure; Section 5 discusses the Pilot Survey; Section 6 describes the K2–HERMES programme; Section 7 presents observing progress through 2016 January (the end of AAT observing semester 15B), Section 8 discusses our potential synergies with other large Galactic survey programmes; and Section 9 presents the GALAH–TGAS (*Tycho-Gaia* Astrometric Solution) catalogue. The overlap between GALAH and *Gaia* (*Gaia* Collaboration et al. 2016) is an extremely important data set. GALAH stars are all in the magnitude range ( $12 \leq V \leq 14$ ) for which *Gaia* parallaxes and proper motions (Lindgren et al. 2016) will be at their best and most complete. Ultimately, GALAH will be able to contribute elemental abundances for a large number of stars with high-precision *Gaia* data, forming a very powerful resource for studying Galactic chemodynamics.

## 2 INSTRUMENTATION: THE HERMES SPECTROGRAPH AND THE 2DF FIBRE POSITIONER

The GALAH survey collects all of its data with the HERMES spectrograph at the AAT. While HERMES is an AAT facility instrument, it was specifically designed to undertake a large Galactic archaeology survey (Freeman 2012). The instrumental requirements for efficiency, wavelength range and spectral resolution were there-

**Table 1.** HERMES bandpasses.

Channel	Wavelength range (Å)
Blue	4713–4903
Green	5648–5873
Red	6478–6737
IR	7585–7887

fore focused on producing spectra rich in information about stellar parameters and chemical abundances, across a wide range of stellar effective temperature, surface gravity and overall metallicity. Details of HERMES design and integration can be found in Barden et al. (2010), Brzeski et al. (2011), Heijmans et al. (2012) and Farrell et al. (2014), and the as-built performance is discussed in Sheinis et al. (2015).

HERMES has four non-contiguous optical bandpasses covering a total of  $\sim 1000$  Å, with wavelength ranges chosen to maximize the information captured for determining stellar parameters and abundances (see Table 1). A series of dichroic beam splitters divides incoming light into the four channels, with a separate volume phase holographic grating and camera for each. The cameras have independent shutters, and can be given different exposure times. This feature is mainly used during flat-field exposures, when the exposure times are set to 180, 180, 120 and 90 s in the blue, green, red and infrared (IR) channels, respectively, to deliver relatively even count levels (averaging between 5000 and 17 000 counts across all fibres and wavelengths in the raw data) in all four cameras. Spectral resolution, as measured from Th–Xe arc lamp exposures, is  $R \sim 28\,000$ . A more detailed analysis of the spectrograph resolving power as a function of position on the detector is given in Kos et al. (2017).

Light is directed into HERMES from the 2dF fibre positioner (Lewis et al. 2002), which can place 400 magnetic ‘buttons’ carrying optical fibres across a circular field of view with a diameter of  $2^\circ$ . It has two field plates with independent fibres, allowing one plate to be configured while the other is being used to observe. Eight of the buttons carry small fibre bundles, which are used to maintain field alignment and telescope guiding, and the remaining 392 are single fibres, which can be allocated to science targets and sky subtraction apertures. 25 fibres are used as sky apertures, and a further 5–10 are typically unavailable for various engineering reasons. As a result, observed GALAH fields usually deliver spectra for around 360 science targets.

2dF is installed at the AAT prime focus, and the fibres run from the telescope top end to the HERMES enclosure on a lower floor of the AAT dome. The fibres are arranged in a pseudoslit at the spectrograph entrance, resulting in spectra on the detector with very similar wavelength range and dispersion. Fig. 1 shows a zoomed-in region of typical raw data from the red channel: a 20-min exposure in GALAH survey field 2235, observed on 2014 August 9. The dispersion direction is horizontal, and the fibres are separated vertically.

The point spread function (PSF) in HERMES varies across the spatial and spectral directions in all four cameras, with the smallest and most symmetric PSF in the centre of the detector and both ellipticity and tilt increasing towards the edges. This produces a small amount of crosstalk between spectra that are adjacent on the detector, which can be removed in data reduction (Kos et al. 2017). In each wavelength channel, HERMES returns spectra with an SNR of 100 per resolution element in one hour of exposure time in median (1.5 arcsec) seeing, for stars with a magnitude near 14 in

**Figure 1.** A portion of a raw HERMES data frame from the red camera. The strong absorption feature near the centre of the image is  $H\alpha$ . The random scatter of anomalous pixels is due to unwanted charged particle hits.

the corresponding filter (the exact limits are  $B = 14.2$ ,  $V = 13.8$ ,  $R = 14.0$  and  $I = 13.8$ ). Spectral response is fairly even across each channel, so (to first order) SNR is not a function of wavelength within each bandpass. This level of instrument efficiency (total throughput  $\sim 10$  per cent) was a design requirement for HERMES, to allow the GALAH survey to be completed in a reasonable amount of observing time.

There have been three known performance issues in the HERMES+2dF system: systematically higher throughput from targets on the northern half of both field plates; randomly distributed saturated points associated with long vertical readout streaks in three of the four cameras; and an inability to bring the red camera (which covers 6478–6757 Å) entirely into focus. The north–south asymmetry in throughput and smaller scale throughput variations between fibres are described in detail in Simpson et al. (2016). It is not immediately clear what drives the north–south asymmetry, though it does not appear to be an issue in the fibres themselves.

The vertical streaks are present in the blue, green and red cameras, but more common in the blue and green. They are believed to be caused by high-energy particles striking the detectors and freeing enough electrons to saturate a small number of pixels. These electrons are trapped low enough in the silicon layer that reading out the detector only partially flushes them out, so that the saturated pixels spawn a perfectly vertical feature that fades over the course of several exposures. The first time a given streak appears it runs away from the readout amplifier, and in all subsequent images it runs towards the readout amplifier. Laboratory testing by the Instrumentation group at the Australian Astronomical Observatory (AAO) has demonstrated that the high index-of-refraction glass in

each camera’s field-flattening lens is likely to be the particle source. Most of the pixels affected by vertical streaks can be handled by the ordinary cosmic ray removal techniques employed in the GALAH data reduction process (Kos et al. 2017).

In all four cameras, focus is achieved by adjusting the detector using actuators that move piston and tip the wavelength (‘spectral’) axis. The perpendicular (‘spatial’) axis was set during HERMES installation and commissioning, and is not movable through instrument software control. During HERMES downtime in 2014 June, the detector in the red camera was tipped noticeably on its spatial axis, and engineering intervention was required. The spatial axis was returned to its original alignment and the piston was returned to its previous range. However, the new range of motion for the spectral axis was offset from the original range, and as a result it was no longer possible for the actuators to move it sufficiently far to bring the red camera fully into focus. This issue was resolved on 2016 August 10 by AAO engineering staff, and the red camera can now be brought into focus as well as it could before 2014 June.

While HERMES does return spectra with SNR of 100 per resolution element in each camera for stars with apparent magnitudes near 14 in the appropriate Johnson–Cousins filter (as described above), only A-type stars, which are rare in the GALAH data set, have colours of zero and could have apparent magnitudes of 14.0 in  $B$ ,  $V$ ,  $R$  and  $I$  simultaneously. GALAH targets are selected based on a  $V$  magnitude calculated from 2MASS  $J$  and  $K$  (as described in Section 3 below), and so we use the mean SNR per resolution element in the green channel spectrum as our figure of merit. As a result, the SNR for each star in each HERMES channel will be a function of its spectral energy distribution. Recent work within our

**Figure 2.** Cumulative histograms of SNR per resolution element for the example data set, with the four HERMES channels drawn in different colours and line styles as described in the text.

team (Ting et al. 2015) finds that increasing the resolution of chemical space by increasing the precision of abundance measurements is critical to large-scale chemical tagging, and that an SNR of at least 100 is required for abundance determinations as precise as 0.02 or 0.03 dex.

Fig. 2 shows cumulative histograms of SNR per resolution element in each HERMES channel as reported by the data reduction software (Kos et al. 2017). This figure shows data for 83 026 unique science targets in a set of 256 regular survey fields with three 20-min exposures (the typical GALAH observing pattern, as described in Section 4) observed between the start of the Pilot Survey (2013 November 16) and the end of AAT Semester 15B (2016 January 30). The blue dash-dotted line represents the blue channel (in which 27 per cent of stars have  $\text{SNR} > 100$  per resolution element), the solid green line the green channel (59 per cent), the dashed red line the red channel (82 per cent) and the dotted black line the IR channel (75 per cent). In this ‘example data set’, there are far more red stars than blue stars, and this will also be true of the full GALAH survey. Therefore, the SNR in the blue channel spectra will typically be lower than in the other three, while the SNR in the red and IR channel spectra are typically similar to each other and higher than in the green channel.

Fig. 3 shows the apparent (non-dereddened) Johnson–Cousins ( $B - V$ ),  $V$  colour–magnitude diagram for the example data set. These data have been binned into hexagons and colour-coded by mean green channel SNR in the bin (left-hand panel) and by mean  $E(B - V)$  reddening in the bin (right-hand panel). Reddening is derived for each star as described in Section 9 below. There are three clear effects to be seen in this figure: first, that redder stars have a higher SNR at a fixed  $V$  magnitude; secondly, that some of the redder stars are simply more reddened rather than intrinsically redder; and finally, that the calculated  $V_{\text{JK}}$  magnitude we used for target selection does not always translate directly into the true Johnson–Cousins  $V$  magnitude, but is moderated by stellar colour and by reddening. Intrinsically bluer stars must have brighter apparent  $V$  magnitudes to be observed by GALAH than intrinsically redder stars. Fig. 4 reinforces this point, showing SNR per resolution element in each HERMES camera in turn versus  $V$  magnitude, colour-coded by ( $B - V$ ) colour. In the blue channel, the bluest stars have the highest SNR, but the SNR for these stars is clearly lower relative to the redder stars in the other three channels.

### 3 INPUT CATALOGUE AND TARGET SELECTION

The GALAH input catalogue is the union of the 2MASS (Skrutskie et al. 2006), APASS (Munari et al. 2014) and UCAC4 (Zacharias et al. 2013) catalogues, with selections for photometric quality and crowding. Because APASS photometry was not available for all of our stars at the start of GALAH observing, we calculate a  $V$  magnitude from 2MASS  $J$  and  $K$  as follows:  $V_{\text{JK}} = K + 2(J - K + 0.14) + 0.382e^{((J-K)-0.2)/0.5}$ . This relation is an accurate fit to intrinsic dwarf colours as derived by Casagrande et al. (2010) and to giant colours from Kučinskas et al. (2005) and Kučinskas et al. (2006) once transformed from the Glass to the 2MASS filter system. The error on  $V_{\text{JK}}$  is larger than 0.2 mag only for some very cool ( $T_{\text{eff}} \leq 3600$  K) stars, which are rare in our sample. All stars with apparent  $V_{\text{JK}}$  magnitude brighter than 14 and Galactic latitude larger than  $5^\circ$  are included in the input catalogue, provided that they have appropriate 2MASS quality flags<sup>2</sup> ( $Q = \text{‘A’}$ ,  $B = \text{‘1’}$ ,  $C = \text{‘0’}$ ,  $X = \text{‘0’}$ ,  $A = \text{‘0’}$ ,  $\text{prox} \geq 6$  arcsec) and no brighter neighbours within a radius of  $V_{\text{neighbour}} = [130 - (10 \times V_{\text{neighbour}})]$  arcsec. This returns 5.99 million stars.

To choose target stars from the input catalogue, we make no selection on colour or reddening, preferring a simple selection function in apparent magnitude ( $12 \leq V_{\text{JK}} \leq 14$ ), which can be straightforwardly inverted to allow interpretation through Galactic models (e.g. Sharma et al. 2014). However, we do make some selections in support of survey science goals: declination,  $\delta$ , is limited to  $-80^\circ < \delta < +10^\circ$ , to maintain an airmass below 1.6 in all observations; Galactic latitude,  $b$ , is restricted to  $|b| > 10^\circ$ , to avoid significant and variable extinction closer to the plane; and the density of targets with  $12 \leq V_{\text{JK}} \leq 14$  must be at least 400 per  $\pi$  deg<sup>2</sup>, to ensure efficient observations with 2dF.

This more restricted set of 3.69 million targets is then tiled to produce 6545 fixed ‘configurations’ of 400 stars each, to allow efficient use of the 2dF fibre positioner. These configurations use the full  $2^\circ$ -diameter field of view in lower density regions, and are more compact in denser regions, to allow a more efficient tiling. In particularly dense regions, multiple configurations can share a single field centre. The tiling strategy will be discussed in more depth in Sharma et al. (in preparation). This survey sample is strongly focused on the thin and thick disc. Using the GALAXIA software (Sharma et al. 2011), which simulates synthetic observation of the Milky Way using a Besançon model (Robin et al. 2003) and Padova isochrones (Bertelli et al. 1994; Marigo et al. 2008), we predict that 75 per cent of these stars belong to the thin disc, 24 per cent to the thick disc, 0.9 per cent to the bulge and 0.1 per cent to the halo.

Although we do not make any colour selections for survey science targets, we anticipate that our spectroscopic analysis will be most accurate and successful for stars with effective temperature between 4000 and 7000 K. Stellar parameters and abundances will be more difficult to determine for stars outside that range: in hot stars, because of a lack of Fe and Ti lines in the HERMES wavelength ranges, and in cool stars, because of an overabundance of molecular features. We anticipate that the ongoing development of model atmospheres for cool stars (e.g. Allard 2014) will allow us to analyse those targets in the future. The lack of colour selection will also result in a small minority of stars that are observed being

<sup>2</sup>These flags are defined at [http://www.ipac.caltech.edu/2mass/releases/allsky/doc/sec2\\_2a.html](http://www.ipac.caltech.edu/2mass/releases/allsky/doc/sec2_2a.html).

**Figure 3.** Apparent  $(B - V)$ ,  $V$  colour–magnitude diagram for the example data set, binned into hexagons and colour-coded by mean green channel SNR per resolution element in each bin (left-hand panel) and mean  $E(B - V)$  reddening in each bin (right-hand panel).

**Figure 4.** SNR per resolution element for all four HERMES channels versus apparent  $V$  magnitude for the example data set, colour-coded by  $(B - V)$  colour. Bluer stars have higher blue channel SNR, but their SNR drops relative to the redder stars in the redder channels.

found at extreme points of evolution for which our analysis will not work at all, e.g. T Tauri stars and white dwarfs.

#### 4 OBSERVING PROCEDURE

As described above, HERMES meets the design requirement for a SNR of 100 per resolution element when observing a target with  $V_{JK} = 14$  for one hour in median seeing. This sets the basic unit of GALAH survey observing at one hour of integration time per field, with some adjustments as required depending on the observing conditions. The nominal GALAH observing procedure is to take three 20-min exposures for each configuration, with an additional 20 min if the seeing is between 2 and 2.5 arcsec or an additional 60 min if the seeing is between 2.5 and 3 arcsec. We find that these adjustments to the exposure time are typically sufficient to raise the SNR to the required level (as discussed in Sheinis et al. 2015).

Typical overhead is 25 per cent of the on-target observing time for the standard  $3 \times 20$ -min exposures. We spend 180 s each for flat-field and Th–Xe arc exposures (taken directly before or after the science data), 71 s per readout, and 2–5 min to slew the telescope, tumble the 2dF top end so that the other field plate is available for observing, and acquire the next science field. It takes  $\sim 40$  min to configure a full 2dF plate, which makes the total observation block time of  $\sim 60$  min well suited to this efficient observing strategy, ensuring no observing time is lost due to plate reconfiguration.

There are a few special requirements for GALAH survey observing. To minimize the effects of chromatic variation and distortion in the 2dF corrector optics (Cannon et al. 2008), the change in airmass during a nominal 60-min GALAH observation will ideally be less than 0.05. Because of the range of declination for GALAH targets, this translates into a strong preference that GALAH fields always be observed within 1.5 h of the meridian, unless there are no fields

available at an appropriate hour angle. We also require that the field being observed is at least  $30^\circ$  from the Moon, since we are mainly observing in bright time, and that there are no bright Solar system planets within the field, since they have caused trouble in previous 2dF surveys. Stars from the input catalogue in the range  $11 < V_{JK} < 12$  are used as ‘fiducial’ stars for field alignment and guiding during normal survey observations. We have developed software to select configurations for survey observations, and to keep track of which of the 6545 survey configurations have been observed. This `OBSMANAGER` software produces a list of configurations that meet the above criteria at a user-supplied date and time, produces the files used to configure the 2dF fibres and tracks observational progress.

The 2dF configuration files produced by `OBSMANAGER` contain lists of science targets, fiducial stars and sky positions, but they do not include specific allocations of targets to individual 2dF fibres. This information is added with the `CONFIGURE` program (Miszalski et al. 2006), which uses a simulated annealing algorithm to assign the fibres to targets as efficiently as possible while also respecting the limits on where in the field each individual fibre can be placed, allocating a user-determined number of fibres to sky apertures, and maximizing the number of guide fibres placed in the field of view.

Observations are made semiclassically. Although `OBSMANAGER` could choose observable fields and produce setup files autonomously, the software controlling the 2dF fibre positioner and the HERMES spectrograph is not amenable to scripted operations, and the hardware occasionally needs human intervention. Decisions relating to variable seeing or weather also benefit from the intuition of an experienced observer. GALAH observations typically involve one or two astronomers from the science team, one of whom has significant experience observing with 2dF. These observers run `OBSMANAGER`, select configurations to observe, configure 2 dF, initiate all exposures, maintain raw data organization and keep logs. In addition to observing at the AAT, observations are also routinely conducted remotely from the AAO offices in North Ryde and from remote observing facilities at Mt. Stromlo Observatory in Canberra and the International Centre for Radio Astronomy Research in Perth.

## 5 GALAH PILOT SURVEY

The GALAH Pilot Survey, which ran from 2013 November 16 until 2014 January 19, was a joint science verification and early science programme, concurrent with HERMES commissioning. There were four main projects in the Pilot Survey: *Gaia* benchmark stars, thin/thick disc normalization, star clusters and asteroseismic targets observed by the *CoRoT* satellite. These projects covered a wide range of possible uses for HERMES, while allowing the commissioning and science verification teams to test critical functions of both the instrument and the GALAH software. The data set and goals for each of these projects are described in this section; results will be published separately as each project progresses. Because of the restricted range in target right ascension, the observing procedure was not as strict for the Pilot Survey as for the main survey, and fields were observed at hour angles between  $-01^{\text{h}}45^{\text{m}}$  and  $+06^{\text{h}}30^{\text{m}}$  (though this extreme case was for a circumpolar field).

### 5.1 *Gaia* benchmark stars

We have observed 26 of the 34 stars designated as benchmark stars for the *Gaia* mission (Heiter et al. 2015). Since these stars are all quite bright, we observed them with a single 2dF fibre rather than as part of regular survey configurations. Exposure times were short, typically less than 120 s, such that telescope tracking was sufficient

to maintain the alignment of the star on the fibre. These stars have weakly model-dependent measurements of their stellar parameters based on angular diameter, bolometric flux and parallax, which can be used to test the accuracy of spectroscopic stellar parameter determinations. They are also an excellent (if small) data set for cross-survey comparison and calibration, since they are well distributed across parameter space and evolutionary state, and across the sky. GALAH stellar parameters and metallicities for *Gaia* benchmark stars will be discussed in a future paper on the data analysis pipeline.

### 5.2 Thin/thick disc normalization

The largest amount of observing time in the Pilot Survey was spent on a programme to investigate the normalization (that is, the ratio of thin-to-thick-disc stars in the mid-plane) and rotational lag between the Galactic thin and thick discs. A clear chemical separation in the  $[\alpha/\text{Fe}]$ – $[\text{Fe}/\text{H}]$  abundance plane can be made between these two populations (see e.g. Adibekyan et al. 2012; Bensby, Feltzing & Oey 2014; Hayden et al. 2015). With HERMES spectra, we can study the overall  $[\alpha/\text{Fe}]$ – $[\text{Fe}/\text{H}]$  plane and the behaviour of individual alpha elements in the thin versus the thick disc, since they do not all have the same nucleosynthetic origins.

The intended observational targets of this project were red-giant-branch stars  $\sim 3.3$  kpc from the Sun. They were selected from the 2MASS catalogue with  $(J - K) > 0.45$  for  $10 < K < 12.2$  and  $(J - K) > -0.1$  for  $9 < K < 10$  and the same quality flags as the GALAH input catalogue. This programme took observations of 9847 stars in 29 fields with Galactic longitude  $l \sim 270^\circ$  and latitude  $b$  of  $-16^\circ$ ,  $-22^\circ$ ,  $-28^\circ$ ,  $-35^\circ$  and  $-42^\circ$ . Because targets were chosen based on photometry, there was contamination by foreground dwarfs. Separating dwarfs and giants at a surface gravity of  $\log(g) = 3.8$ , the contamination was typically 36 per cent, rising for stars further from the plane. This is somewhat lower than the dwarf/giant ratio we find in regular GALAH survey observations in the disc, indicating that the colour selection was helpful in isolating giants. The results of this project will be presented in Duong et al. (in preparation).

### 5.3 Globular and open clusters

Globular and open star clusters provide important anchor points for large stellar surveys like GALAH (e.g. Smolinski et al. 2011; Anguiano et al. 2015). We use stars in globular and open clusters to confirm that our analysis pipelines are returning reasonable and consistent values for stellar parameters and abundances, to cross-calibrate with other large survey projects, and as benchmarks for chemical tagging methods.

The Pilot Survey included targeted observations of stars in four globular clusters (NGC 288, NGC 362, NGC 1851 and 47 Tucanae) and the open cluster M67. These clusters were selected to provide a broad coverage of metallicity, and for observability with HERMES during the Pilot Survey: right ascension,  $\alpha$ , in the range  $0^{\text{h}} < \alpha < 9^{\text{h}}$  and distance modulus,  $(m - M)_V$ , less than 15.5. These observations were taken differently from normal GALAH survey observations, with the apparent magnitude range extended as faint as  $V = 16$  and the total exposure times extended as long as 6 h per field for the more distant clusters to capture as many stars as possible from the red giant branch, red clump and horizontal branch. The globular clusters  $\omega$  Centauri and NGC 7099 were also specifically targeted after the end of the Pilot Survey, to provide additional well-studied anchors for our analysis. Similar to the Pilot Survey clusters, the apparent magnitude range extended to  $V = 17$  and the exposure times were as long as 6.3 h.

**Table 2.** Data for globular and open clusters observed intentionally by GALAH.

Cluster	$\alpha$	$\delta$	$(m-M)_V$	[Fe/H]	$N_{\text{stars}}$	$V$	$t_{\text{exp}}$ (s)	Obs. dates

Targets in the Pilot Survey clusters were chosen from cluster members identified in previous studies (Carretta et al. 2009; Yong et al. 2009; Simpson & Cottrell 2013; Marino et al. 2014; Navin, Martell & Zucker 2015; Da Costa 2016, private communication; Stetson, private communication). Targets in  $\omega$  Cen were taken from Bellini et al. (2009), and in NGC 7099 from Da Costa (2016). We were only able to observe between 10 and 173 cluster members in any single configuration, given the magnitude limits and the limitations of the fibre positioner (2dF fibres cannot be placed closer together on the sky than 30 arcsec). All together, we observed between 10 and 394 stars total per cluster, typically in the outer regions. Table 2 lists coordinates, distance moduli, metallicity (taken from Heiter et al. 2014 for M67 and from the 2010 edition of Harris 1996 for the globular clusters), number of stars observed,  $V$  magnitude range, exposure time and dates of observation for all of the globular and open clusters observed in this targeted fashion. Fig. 5 shows colour–magnitude diagrams for all of these clusters, with stars observed by GALAH highlighted as red circles and stars from the 2MASS Point Source Catalogue within 10 arcmin of cluster centre shown as smaller grey circles.

Fig. 6 shows the  $(V, B - V)$  colour–magnitude diagram for  $\omega$  Centauri. All stars within 10 arcmin with a membership probability above 0.9 are shown as small grey circles, and stars observed by GALAH are highlighted as larger coloured circles. In the left-hand panel, they are colour-coded by our derived effective temperature, and in the right-hand panel they are colour-coded by our derived metallicity. The optical photometry is taken from Bellini et al. (2010), which we also used for spectroscopic target selection. Our derived  $T_{\text{eff}}$  follows expected trends, and our derived [Fe/H] values show an overall similarity to the complex morphology described in Johnson & Pilachowski (2010), with the reddest giant branch being the most metal-rich.

In addition to the stars observed intentionally during the Pilot Survey, a number of cluster members have been observed serendipitously in GALAH survey fields. The upper panel of Fig. 7 shows a colour–magnitude diagram for the 318 stars observed in survey field 51 (red circles), and the lower panel shows the spatial distribution of targets for that field, with a circle marking the field of view of 2dF. The concentration of targets near 47 Tuc is clear in the southwestern quadrant of the field, and in the colour–magnitude plane the cluster red giant branch can be seen mixed together with the broader distribution of field stars. 2MASS photometry for all stars within 10 arcmin of the centre of 47 Tuc is also shown as small grey circles to guide the eye. Membership for serendipitously observed cluster stars can be verified with radial velocity and proper motion. In addition to these serendipitously observed 47 Tuc stars, we have identified stars belonging to NGC 362, M67, NGC 2516, NGC 2243, NGC 6362 and the Pleiades within regular survey fields, and

**Figure 5.** Near-IR colour–magnitude diagrams for the seven open and globular clusters observed intentionally. Red points are the cluster members, and smaller grey points are all stars in the 2MASS Point Source Catalogue within 10 arcmin of cluster centre.

**Figure 6.** The  $(V, B - V)$  colour–magnitude diagram for  $\omega$  Centauri, colour-coded by GALAH effective temperature (left-hand panel) and metallicity (right-hand panel). All stars within 10 arcmin of the cluster centre, with membership probability from Bellini et al. (2010) above 0.9, are shown as smaller grey circles. Both  $T_{\text{eff}}$  and  $[\text{Fe}/\text{H}]$  behave as expected, both in terms of range and trends.

**Figure 7.** Near-IR colour–magnitude diagram for the stars in GALAH survey field 51. Red points are all stars observed in the field, and smaller grey points are all stars in the 2MASS Point Source Catalogue within 10 arcmin of the centre of 47 Tuc, similar to Fig. 5. Stars that are likely cluster members based on their photometry can be confirmed using radial velocities, stellar parameters and abundances determined from the spectra.

we anticipate that future survey observations will provide serendipitous observations of many more cluster members and extratidal stars associated with star clusters (e.g. Navin et al. 2015).

#### 5.4 *CoRoT* targets

The intersection of asteroseismic and spectroscopic data opens a number of new possibilities for Galactic archaeology. Prior to 2015, the only large-scale asteroseismic mission with targets that could be observed from the Southern hemisphere was *CoRoT* (Auvergne et al. 2009). *CoRoT* observed one large region in the direction of the Galactic Centre and one towards the anticentre, both at declination near zero, potentially providing common targets for GALAH and other ongoing Galactic archaeology surveys. We observed 2218 stars in six configurations in the *CoRoT* anticentre fields LRa01, LRa05 and LRa07 as part of the Pilot Survey, with a simple  $12 < V_{\text{JK}} < 14$  mag selection to match the target selection in the main GALAH survey. Of these, 1526 have successfully been processed through the GALAH analysis pipeline (as described in Section 9 below). We find that 737 of these stars have surface gravity below 3.5, making them ideal for asteroseismic interpretation. Results from this project will be presented in Anguiano et al. (in preparation).

## 6 THE K2–HERMES PROGRAMME

Following the failure of a second reaction wheel onboard the Kepler spacecraft in 2013, the extremely precise pointing that enabled its photometric monitoring work in a single Northern field was lost, and the spacecraft was repurposed to an observational programme along the ecliptic that enabled it to regain its fine pointing precision using only the two remaining reaction wheels and regular thruster firings. A series of 80-d observing ‘campaigns’ along the ecliptic were laid out, and the community was invited to propose targets for this ‘K2’ mission. The data acquired by K2 are useful both for asteroseismology and for transiting exoplanet surveys.

There is tremendous potential in combining asteroseismic information with stellar surface temperature and composition data from photometry and spectroscopy (e.g. Miglio et al. 2013; Casagrande et al. 2016), bringing a new level of precision to determinations of stellar age, mass, radius and surface gravity for red giant stars. Combined asteroseismic and spectroscopic data sets allow us to study stellar populations on a Galactic scale (e.g. Stello et al. 2015;

**Figure 8.** Map of GALAH survey progress through 2016 January 30. Grey circles are unobserved survey fields, pink are regular survey fields that have been observed, cyan are fields observed during the Pilot Survey, blue are fields observed by the K2-HERMES programme, and purple are fields observed for the targeted *Tycho-2* bright-star subproject.

Martig et al. 2016; Sharma et al. 2016). They also make asteroseismic data useful across a broader range of stellar metallicity by providing crucial calibrations for the scaling relations used to interpret stellar oscillations (Epstein et al. 2014). In addition, stellar parameters obtained from spectroscopy are critical for determining the sizes of the transiting planet candidates detected by K2, because uncertainties in planet size are dominated by uncertainties in the stellar radius (e.g. Kane 2014; Wittenmyer et al. 2005). Photometrically derived stellar radii such as those from the *Kepler* Input Catalogue have been shown to have uncertainties of up to  $\sim 40$  per cent for solar-type stars (e.g. Verner et al. 2011; Everett et al. 2013; Bastien, Stassun & Pepper 2014), and similar uncertainties apply for the majority of K2 targets that have been classified in the Ecliptic Plane Input Catalogue (Huber et al. 2016). When high-resolution, high S/N spectra are used in combination with transit measurements, planetary radii can be determined to precisions of 10–15 per cent (e.g. Silva Aguirre et al. 2015; Weiss et al. 2016).

Galactic archaeology target proposals for K2, spearheaded by GALAH team members S. Sharma and D. Stello, have been very successful, with typically 5000 targets in each K2 observing campaign (though not all of these targets will turn out to be giants). Through a separate K2-HERMES observing programme at the AAT (AAT 15A/03, 15B/01, PI Wittenmyer; AAT 15B/03, 16A/22, PI Sharma), many of these targets as well as potential exoplanet hosts are now being observed using similar procedures as for GALAH, enabling beneficial collaboration between GALAH and the K2-HERMES programme. In exchange for data reduction and processing with the GALAH pipeline, K2-HERMES data are incorporated into the GALAH survey data base. K2-HERMES stars with asteroseismically derivable parameters will be quite helpful in the testing and refinement of the GALAH analysis pipeline.

The K2 field of view consists of 19 separate square ‘CCD modules’ covering  $4 \text{ deg}^2$  each, and the K2-HERMES fields lie at the centre of each CCD module’s field of view. The spectroscopic target selection is different in each K2-HERMES field based on its Galactic coordinates, targeting different stellar populations in different lines of sight. K2-HERMES configurations typically cover a wider range in apparent magnitude than GALAH survey fields. As with the survey fields, K2 fields are observed within 90 min of the meridian. As of 2016 January 30, the K2-HERMES programme has observed 31 365 stars.

**Figure 9.** Cumulative histogram of the number of stars observed versus MJD, with colours denoting different survey subsets (dashed pink: main survey; dash-dotted dark blue: K2-HERMES; dotted cyan: Pilot Survey; dashed purple: targeted *Tycho-2* stars; solid purple: serendipitous *Tycho-2* stars). The vertical axis on the left is for the main survey, and the vertical axis on the right is for the other projects.

## 7 OBSERVATIONAL PROGRESS

With a large allocation of time (26 nights for the Pilot Survey between 2013 November 16 and 2014 January 19 and 70 nights per year for the full survey starting in 2014 February) and a highly multiplexed spectrograph, GALAH observing progress has moved quickly despite poorer-than-average weather. Our data rate is 4.2 stars per minute spent on-sky, yielding roughly 50 000 stars per semester. Fig. 8 is an equatorial-projection map of observing progress through 2016 January 30. In this map, grey circles are unobserved survey fields, pink are regular survey fields that have been observed, purple are fields observed for the *Tycho-2* bright-star subproject (described in Section 9 below), blue are fields observed by the K2-HERMES programme and cyan are fields observed during the Pilot Survey. The number of observable regular survey fields varies strongly with right ascension, with all survey fields in the range  $23^{\text{h}} \leq \alpha \leq 4^{\text{h}}$  already observed once.

Fig. 9 is a cumulative histogram of the number of stars observed from the start of the Pilot Survey through 2016 January 30 in each of those programmes, in fortnightly bins. Since there are significantly more stars that have been observed for the regular survey than the

other programmes, the  $y$ -axis on the left is for the regular survey, and the  $y$ -axis on the right is for the Pilot Survey, K2–HERMES stars and *Tycho-2* bright stars. The number of regular survey stars is shown with a pink dashed line, the number of Pilot Survey stars is shown with a cyan dotted line, the number of K2–HERMES stars is shown with a blue dash–dotted line and the number of *Tycho-2* bright stars is shown with a purple solid line (*Tycho-2* stars observed serendipitously during other observations) and a purple dashed line (targeted bright-star fields). The Pilot Survey starts first and runs for a few months, the regular survey and the K2–HERMES programme start shortly before the Pilot Survey ends and the targeted *Tycho-2* bright-star observations begin later. Through 2016 January 30 we have observed 209 345 stars in the main survey, 12 910 stars in the various Pilot Survey programmes and 11034 *Tycho-2* stars (4448 targeted and 6586 observed serendipitously), and an additional 31 365 stars have been observed by the K2–HERMES programme.

## 8 SURVEY SYNERGIES

The wide sky coverage of the GALAH survey provides significant overlap with several other large-scale surveys. This creates important synergies, allowing us to link our thorough local sample with the astrometric measurements from the *Gaia* mission, the pencil-beam *in situ* halo samples of the *Gaia*–ESO and APOGEE surveys, the thorough *Gaia*–ESO coverage of open clusters, the low-latitude disc sample from APOGEE and a significant fraction of the very large sample of the Radial Velocity Experiment (RAVE) survey.

The *Gaia* satellite (Lindgren & Perryman 1996; Prusti 2012), launched in late 2013, is collecting high-precision astrometry and photometry for stars with apparent magnitudes  $5.7 < V < 20$  as well as moderate-resolution spectroscopy near the near-IR calcium triplet and low-resolution spectrophotometry for stars down to  $V = 17$ . *Gaia*'s full catalogues will be revolutionary for our understanding of the phase-space structure of the Galaxy, as well as providing spectrophotometry and basic stellar parameters for as many as one billion stars. Perhaps the most important synergy we have is with *Gaia*, as the entire GALAH input catalogue is within the brightest 1 per cent of *Gaia* targets, which will have parallax uncertainties less than  $10 \mu\text{as}$  and proper motion uncertainties of less than  $10 \mu\text{as yr}^{-1}$ , corresponding to 1 per cent distance errors and  $0.7 \text{ km s}^{-1}$  velocity errors at 15 kpc. Coupling the unprecedented abundance detail of GALAH with the six-dimensional phase-space positions and velocities that can only be measured by *Gaia* will allow us to identify chemically homogeneous groups of stars that also match in age and orbital properties, revealing the process of star formation and chemical evolution in the Galaxy.

The *Gaia*–ESO Survey (GES; Gilmore et al. 2012; Randich, Gilmore & *Gaia*-ESO Consortium 2013) is another ongoing Galactic archaeology survey project, using the GIRAFFE spectrograph (Pasquini et al. 2000) at the Very Large Telescope at the European Southern Observatory in Chile to collect high-resolution ( $R \sim 26000$ ) spectra for 100 000 stars, primarily in the halo and in star clusters. A smaller sample of brighter stars is also being observed at higher resolution ( $R \sim 47000$ ) with the UVES spectrograph (Dekker et al. 2000). Because of the wavelength regions accessible to the multiobject modes of GIRAFFE and UVES, and the resolution of the spectra they produce, GES can determine stellar parameters and abundances for as many as 15 and 34 elements, respectively, per star.

The APOGEE survey and its follow-up project, APOGEE-2, are components of the third and fourth iterations, respectively, of the

SDSS. APOGEE targeted over 150 000 red giants across the disc, bulge and halo, with a regular grid pattern across the sky. APOGEE observations were carried out from Apache Point Observatory in the United States, and APOGEE-2 will continue observations from the same observatory and begin a Southern observing campaign using a duplicate spectrograph at the Irénée du Pont telescope at Las Campanas Observatory in Chile. This survey's unique advantage is that its wavelength coverage is entirely in the IR ( $1.51\text{--}1.70 \mu\text{m}$ ), reducing the line-of-sight extinction and allowing observations of stars much closer to the Galactic plane, including stars on the far side of the bulge. APOGEE spectra have a resolution of  $R \sim 22000$ ; the most recent data release<sup>3</sup> includes abundances for up to 21 elements per star (García Pérez et al. 2016).

The large telescope and excellent site at Paranal allow GES to observe fainter stars than those targeted by GALAH, enabling the capture of a larger sample in the bulge and the *in situ* halo, albeit with a pencil-beam distribution. APOGEE also typically targets stars at larger distances than GALAH does, but perhaps more importantly it includes a significant sample of stars in and near the plane of the Galaxy. The combination of GALAH, GES and APOGEE data will enable science that cannot be done by any one of the surveys alone. Potential examples are studies of radial and vertical trends in the thin disc that use the local GALAH sample as an anchor and the more distant APOGEE and GES samples as probes. It will be critical to bring the abundance results of these different projects on to the same scale to allow this type of cross-survey study.

There is some observational overlap designed in to GALAH, GES and APOGEE, despite their different selection functions, to facilitate this cross-calibration. The Southern extension of APOGEE-2 will make cross-calibration between GALAH and APOGEE much more straightforward, and APOGEE-2 observations are planned to provide a set of stars that comprehensively cover the parameter space of GALAH and APOGEE stars. We have already identified a serendipitous survey overlap of 185 stars with GES, evenly split between UVES and GIRAFFE observations, and a serendipitous overlap of 664 stars with APOGEE, mainly in the K2 ecliptic campaign fields and *CoRoT* Galactic anticentre regions. The data-driven approach of THE CANNON (Ness et al. 2015) will be central to the cross-calibration effort (e.g. Ho et al. 2016), and its capabilities in this area have already been demonstrated in Ness et al. (2016).

The RAVE (Kordopatis et al. 2013) survey is an important precursor to the current generation of Galactic archaeology surveys. RAVE took  $R \sim 7500$  spectra in a small wavelength range near the calcium triplet for nearly 500 000 stars with  $9 < I < 12$ . While the original plan was to determine radial velocities and basic stellar parameters from these data, the RAVE team has shown that they can also derive several elemental abundances and probabilistic distances (Zwitter et al. 2010; Boeche et al. 2011; Kordopatis et al. 2011; Binney et al. 2014). The development of automated spectrum analysis pipelines has benefited from the work of the RAVE team and their goal of maximizing the amount of information to be derived from their spectra. A large fraction of the RAVE sample falls into GALAH's input catalogue, since both are Southern-sky surveys primarily using apparent magnitude for target selection. There are 9388 RAVE stars in the data set considered in this paper. Having GALAH observations of a large number of RAVE stars provides an extremely large comparison set for GALAH radial velocities, and will enable detailed follow-up and extension of important RAVE

<sup>3</sup> <http://www.sdss.org/dr13/>

**Table 3.** The GALAH–TGAS catalogue. The full catalogue is available as Supporting Information online; a portion of the table is published here for guidance as to form and content.

studies of Galactic dynamics and structure (e.g. Ruchti et al. 2011; Antoja et al. 2012; Siebert et al. 2012; Williams et al. 2013).

SkyMapper (Keller et al. 2007) is an Australian synoptic survey project imaging the Southern sky in six photometric bands. Its particular advantage is the inclusion of a Strömgren-like  $u$  filter that captures the Balmer jump and a narrow  $v$  filter that spans the Ca II H&K lines, similar to the DDO38 filter. Colour indices including these filters can be constructed to be quite sensitive to either surface gravity or metallicity (e.g. Howes et al. 2014; Keller et al. 2014). SkyMapper photometry will be a useful tool for a number of GALAH science goals, including the identification of very metal-poor stars, confirmation of star cluster membership and the study of interstellar reddening through comparison of stellar effective temperatures derived photometrically and spectroscopically. We have already identified roughly 60 000 stars in common between GALAH and the SkyMapper Early Data Release, which includes objects from their ‘short survey’ of relatively bright targets. We expect that ultimately all GALAH stars will be in the SkyMapper catalogue.

## 9 *Tycho-2* STARS AND *Gaia* DR1

The *Tycho-2* catalogue (Høg et al. 2000) contains positions and magnitudes for 2.5 million stars. Although the full precision of the astrometric solution for the full *Gaia* data set can only be reached with several years of data, combining the *Tycho-2* catalogue with the first year of *Gaia* data (at an epoch 24 years later) allows a precise solution for positions ( $\sigma \leq 0.75$  mas), parallaxes ( $\sigma \leq 0.64$  mas) and proper motions ( $\sigma \leq 3.19$  mas yr $^{-1}$ ) for all the *Tycho-2* stars (TGAS), as described in Michalik et al. (2014) and Michalik, Lindgren & Hobbs (2015).

In anticipation of the first *Gaia* data release and the TGAS work, GALAH has prioritized observations of *Tycho-2* stars, generating 330 special configurations for fields within the footprint of the main GALAH survey that contain at least 225 stars from *Tycho-2* in the range  $9 < V_{\text{JK}} < 12$ . These configurations are suggested by the OBSMANAGER software for observation during evening and morning twilight. Because these stars are brighter than GALAH survey targets, the standard exposure times are shortened to  $3 \times 6$  min instead of  $3 \times 20$  min. As of 2016 January 30, we have observed 4448 *Tycho-2* stars in 26 of these targeted fields. An additional 6586 stars from the *Tycho-2* catalogue have been observed as part of our regular survey fields.

We have identified the *Tycho-2* stars observed in GALAH through 2016 January 30, and made a portion of the current GALAH-derived quantities for those stars publicly available ahead of the first *Gaia* data release on 2016 September 14. This catalogue contains 10 680

observations of 9860 stars, of which 7894 stars are in the *Gaia* DR1 TGAS catalogue. Our goal in publishing this GALAH–TGAS catalogue is to facilitate the exploitation of *Gaia* DR1 and to demonstrate the quality of GALAH-derived quantities with a data set that will be extremely well studied in the near future. Table 3 lists ID numbers from GALAH, *Tycho-2* and 2MASS, right ascension and declination from UCAC4,  $T_{\text{eff}}$ ,  $\log(g)$ , [Fe/H],  $[\alpha/\text{Fe}]$ , radial velocity, distance modulus and  $E(B - V)$  reddening for the first 10 stars in the catalogue; the full table is available on the Vizier catalogue service and in the online material for this paper. The full table includes analysis results for 3801 observations of 3675 *Tycho-2* stars in targeted fields and 6879 observations of 6185 serendipitously observed *Tycho-2* stars for which we have successfully determined stellar parameters.

Barycentric-corrected radial velocities are determined through cross-correlation against a grid of AMBRE model spectra (de Laverny et al. 2012), as described in Kos et al. (2017). We use the HERMES blue-, green-, and red-arm spectra for radial-velocity determination, but not the IR-arm spectra due to a relative lack of stellar features and a large number of telluric features. Adopted radial velocities are the mean of the values in the three arms, and the reported uncertainty is the standard deviation. Note that if the radial velocity measured from one arm is notably discrepant, e.g. is further from the mean than two times the difference between the measurements from the other two arms, it is excluded from the final radial-velocity estimate. 98 per cent of all of our GALAH stars have a standard deviation of less than 0.6 km s $^{-1}$ .

The typical error on the radial velocity combined from the measurements in the three arms is a combination of systematic errors. One main contributor is the uncertainty that comes from the wavelength calibration itself. Spectra have been wavelength calibrated using a spectrum of a Thorium–Xenon arc lamp. Xenon lines dominate these spectra, and we had to calibrate their wavelengths from the HERMES spectra themselves because of a lack of reliable linelist information in the literature. The wavelength calibration is therefore only accurate to 0.1–0.5 km s $^{-1}$ , as can be seen in fig. 12 of Kos et al. (2017). The systematic offset in radial velocity between different arms is very low on average, typically  $-0.16$  km s $^{-1}$  between the green and blue arms and  $-0.25$  km s $^{-1}$  between the red and blue arms. For any given star, there is a  $1\sigma$  probability that the difference in radial velocity between any two arms will be as large as 0.5–0.75 km s $^{-1}$ , depending on the arms. This can be seen in fig. 18 of Kos et al. (2017).

We have compared GALAH radial velocities to a number of sources in the literature. As presented in Kos et al. (2017), the values show good agreement with literature values for four clusters, M67, NGC 1851, NGC 288 and 47 Tuc. We can also verify our

**Figure 10.** A comparison of GALAH radial velocities with values from RAVE (left-hand panel) and APOGEE (right-hand panel). The  $x$ -axis is the GALAH radial velocity in  $\text{km s}^{-1}$  while the  $y$ -axis is the difference between the GALAH value and that from the other survey, in the sense (GALAH–other). Colour, as denoted by the bar, indicates the number density of stars. The right-hand portion of each figure shows the distribution of the difference in radial velocity. The top-left corner lists the mean and standard deviation in radial-velocity difference.

radial-velocity accuracy by comparing GALAH values with those from other surveys. Through the end of 2016 January (the time period discussed in this study), there are 9388 and 664 targets that have also been observed by RAVE and APOGEE (RAVE DR4: Koronopatis et al. 2013; SDSS DR10: Ahn et al. 2014), respectively. As the survey continues, this will prove to be an invaluable sample for data base cross-comparison. Currently, it provides a useful comparison set for our radial velocities. The left-hand panel of Fig. 10 shows the distribution of the difference in velocities between RAVE and GALAH. For this comparison, we have trimmed the GALAH–RAVE overlap sample to 3434 stars, based on the following quality criteria from the RAVE catalogue (Steinmetz, private communication):

- (i)  $\log g_K > 0.5$  dex
- (ii)  $\text{SNR}_K > 20$
- (iii)  $e\text{HRV} < 10 \text{ km s}^{-1}$
- (iv)  $T_{\text{eff}_K} > 4000 \text{ K}$
- (v)  $\text{CHISQ}_c < 2000$
- (vi)  $c1, c2, c3 = n$
- (vii)  $\text{Algo\_Conv}_K = 0$ .

The mean offset between GALAH and RAVE is  $0.45 \text{ km s}^{-1}$  with a standard deviation of  $1.75 \text{ km s}^{-1}$ . Since RAVE uses lower resolution spectra than GALAH and reports a typical radial-velocity uncertainty of  $2 \text{ km s}^{-1}$ , this is very good agreement. APOGEE is also consistent with GALAH, showing a mean offset of  $0.05 \pm 0.81 \text{ km s}^{-1}$  (Fig. 10, right-hand panel).

For the stellar parameter determination, we use a combination of the spectral synthesis program SPECTROSCOPY MADE EASY (SME; Valenti & Piskunov 1996; Piskunov & Valenti 2016) and the data-driven CANNON by Ness et al. (2015). This approach delivers both accurate and precise parameters and is computationally inexpensive, as THE CANNON takes only 0.13 s to compute seven stellar labels for one spectrum.

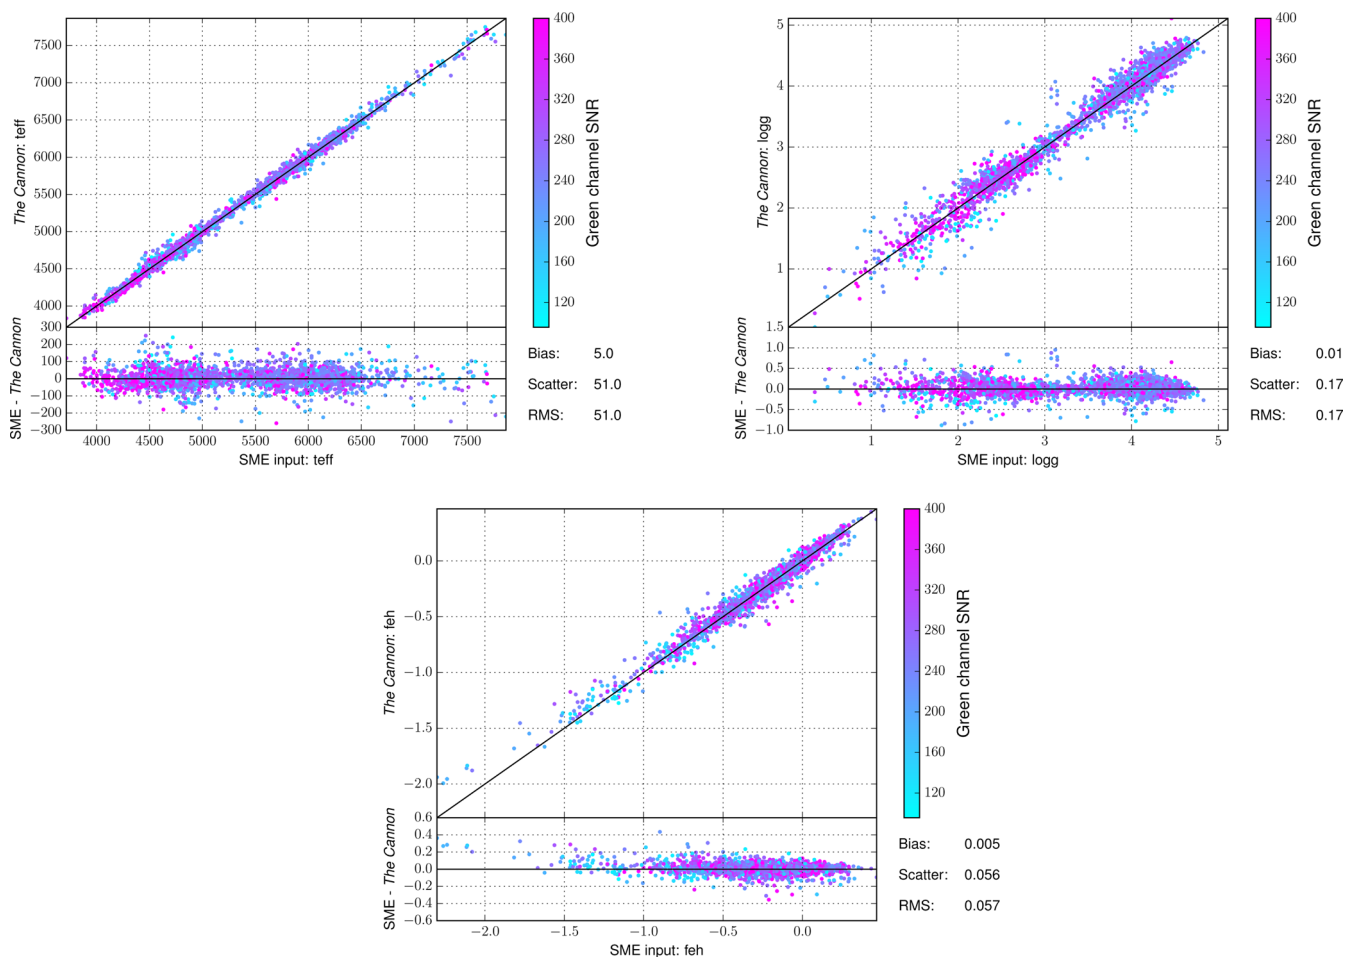

We first use SME to determine stellar parameters and  $[\alpha/\text{Fe}]$  abundances for a subset of 2576 GALAH stars spanning the entire range of parameters covered by the survey. This subsample is then used as the training data set for THE CANNON. To obtain the highest precision and accuracy, this representative training set is comprised of only high-quality spectra ( $\text{SNR} > 95$  per resolution element), as well as high-fidelity validation targets including observed benchmark stars with reliable, independent stellar parameters (Heiter et al. 2015), well studied open and globular cluster stars, and stars with confirmed asteroseismic surface gravities.

Our initial estimates for  $T_{\text{eff}}$ ,  $\log(g)$  and  $[\text{Fe}/\text{H}]$  are determined through cross-correlation against a grid of AMBRE model spectra that is larger and more finely sampled than the grid used for radial-velocity determination, as described in Kos et al. (2017). SME takes these as input and determines the stellar parameters by fit-

ting synthetic spectra to observations, returning optimal parameters corresponding to the minimum  $\chi^2$  (Piskunov & Valenti 2016). The SME synthesis employs MARCS model atmospheres (Gustafsson et al. 2008), and includes NLTE corrections for Fe (Lind, Bergemann & Asplund 2012). The global parameters  $T_{\text{eff}}$ ,  $\log(g)$ ,  $[\text{Fe}/\text{H}]$ ,  $v_{\text{mic}}$ ,  $V_{\text{sin } i}$  and  $v_{\text{rad}}$  are optimized for unblended lines in the spectra, including the  $\text{H}\alpha$ ,  $\text{H}\beta$ ,  $\text{Fe I/II}$ ,  $\text{Sc I/II}$  and  $\text{Ti I/II}$  lines which have reliable atomic data. The optimal global parameters returned by SME are subsequently fixed, and an error-weighted  $[\alpha/\text{Fe}]$  is calculated from  $\chi^2$  optimization for selected lines of  $\alpha$ -process elements Mg, Si and Ti.

THE CANNON then uses the normalized spectra, SME-determined stellar parameters and  $\alpha$ -abundances as labels for the reference set of stars and generates a spectral model of the GALAH spectra at rest-frame wavelength. This generative CANNON model relates the observed flux to the labels provided (the training step) and is used to determine those same labels for all stars in the survey. We find that a second-order polynomial model works well for GALAH spectra. In addition to the SME stellar parameters and abundances, we also include extinction values as a label for THE CANNON, allowing it to take into account the effect of diffuse interstellar bands on some  $\alpha$ -element lines, and thus providing a more accurate final  $\alpha$ -abundance. The extinction,  $A_K$ , is derived as described by Zsawski et al. (2013), using the 2MASS  $H$ -band and WISE 4.5- $\mu\text{m}$  photometry (Skrutskie et al. 2006; Wright et al. 2010). For each star, THE CANNON delivers a set of seven labels consisting of  $T_{\text{eff}}$ ,  $\log(g)$ ,  $[\text{Fe}/\text{H}]$ ,  $v_{\text{mic}}$ ,  $V_{\text{sin } i}$ ,  $[\alpha/\text{Fe}]$  and  $A_K$ . Fig. 11 shows the results of 20 per cent leave-out cross-validation tests demonstrating that THE CANNON is well able to determine the stellar labels to high precision. This test involves omitting a random 20 per cent of the training set, then comparing the parameter values predicted for those omitted stars by THE CANNON with the values determined using SME. We find the following biases and precisions:  $\Delta T_{\text{eff}} = 5 \pm 41 \text{ K}$ ,  $\Delta \log(g) = 0.01 \pm 0.17$  dex,  $\Delta [\text{Fe}/\text{H}] = 0.005 \pm 0.056$  dex. We have provided here a summary of the GALAH spectroscopic analysis pipeline, the details of which will be given in Asplund et al. (in preparation).

Distances are determined using theoretical isochrones, as discussed in Zwitter et al. (2010), assuming that each star undergoes a standard stellar evolution and that its spectrum shows no peculiarities. The latter is checked by morphological classification of spectra which is based on a  $t$ -distributed stochastic neighbour embedding algorithm (Traven et al., in preparation; for description of the algorithm see van der Maaten 2013 and references therein). Absolute magnitudes in Johnson  $V$  and 2MASS  $J$  bands are estimated from theoretical Padova isochrones (Bertelli et al. 2008) with weights determined (as described in Zwitter et al. 2010) using a mass function from Chabrier (2003), a flat prior on ages between 0.5 and 12 Gyr and a flat prior on space density. Stellar parameter values determined from GALAH spectra by THE CANNON algorithm

**Figure 11.** Results from 20 per cent leave-out cross validation tests for  $T_{\text{eff}}$  (upper left),  $\log(g)$  (upper right) and  $[\text{Fe}/\text{H}]$  (lower left), as described in the text. These tests were repeated five times, and data from all five tests are plotted together in this figure, colour-coded by the green channel SNR per resolution element. For each parameter, the upper panel shows CANNON versus SME parameters with a 1:1 correspondence line drawn in solid black, and the lower panel shows the difference between the two as a function of the SME values.

(Ness et al. 2015) are assumed to have a standard deviation of 100 K in temperature, 0.25 dex in gravity and 0.1 dex in metallicity. These error estimates are compatible with differences between parameter values determined by GALAH and APOGEE (Holtzman et al. 2015) for stars observed by both surveys.

Comparison of absolute magnitudes with the apparent  $V$  magnitude from the latest version of the APASS survey (Henden & Munari 2014) and  $J$  magnitude from 2MASS (Cutri et al. 2003) leads to an estimate of the distance modulus as well as reddening along the line of sight, if standard relations  $A_V = 3.1E(B - V)$  and  $A_J = 0.887E(B - V)$  are used. The typical accuracy of the derived distance modulus is 0.4 mag (implying a distance uncertainty of  $\sim 20$  per cent) and the typical accuracy of colour excess is  $\sim 0.04$  mag. Such errors apply to main-sequence (MS) and to red-giant-branch stars, but for the transition region between the MS turn-off and the red giant branch the errors increase considerably. Comparison of our and literature values of distance moduli and reddenings for members of three open clusters (NGC 2243, Pleiades and NGC 2516) and one globular cluster (NGC 6362) confirm such error estimates. GALAH targets are located at least  $10^\circ$  from the Galactic plane, so uncertainties in reddening do not affect derived values of distance modulus significantly. This is confirmed by a median value of just 0.03 mag for the colour excess. Here, we publish spectrophotometric dis-

tances for *Tycho-2* stars, which are much brighter and so closer than typical stars observed by GALAH, where MS stars are generally within 1 kpc from the Sun and red clump stars are at distances of  $\sim 3$  kpc.

The derived stellar parameters for *Tycho-2* stars observed by GALAH appear to be quite reasonable. This can be seen in Fig. 12, which shows effective temperature versus surface gravity, colour-coded by metallicity (left-hand panel) and binned into hexagons and colour-coded by the number of stars per bin (right-hand panel). As one might expect, there is a clear gradient in metallicity across the red giant branch and the upper MS. There are few metal-poor stars ( $[\text{Fe}/\text{H}] < -1.5$ ), and the majority of the stars are on the MS, indicating that these stars belong almost entirely to the Galactic disc.

Fig. 13 shows colour-magnitude diagrams in dereddened ( $B - V$ ) and absolute  $M_V$ , colour-coded by metallicity (left-hand panel) and distance (right-hand panel). Since these stars are fairly bright, their distribution across the Milky Way is somewhat limited relative to the full GALAH survey. This can be seen in Fig. 14, which shows histograms of metallicity (left-hand panel) and distance (right-hand panel). Although the stars in the GALAH-TGAS catalogue do span the full sky coverage of the GALAH survey (as can be seen in Fig. 15), they are mainly members of the thin disc: they have relatively high metallicities and are located within 2 kpc of the Sun.

**Figure 12.** Stellar parameters  $T_{\text{eff}}$  and  $\log(g)$  for stars in the GALAH–TGAS catalogue, colour-coded by metallicity (left-hand panel), and binned into hexagons and colour-coded by the number of stars per bin (right-hand panel).

**Figure 13.** Absolute colour–magnitude diagram for stars in the GALAH–TGAS catalogue, colour-coded by metallicity (left-hand panel) and distance (right-hand panel).

**Figure 14.** Histograms of metallicity (left-hand panel) and distance (right-hand panel). The distance histogram is shown on a logarithmic scale to enhance the visibility of stars at larger distance, since the majority of stars in the GALAH–TGAS catalogue are quite nearby.

## 10 SUMMARY

The GALAH survey has made significant progress towards its goal of observing one million stars in the Milky Way over its first two years of survey observing. Up to 2016 January 30, we have observed 209 345 stars in the main survey, 845 targeted stars in globular and open clusters, 2218 stars in the *CoRoT* anticentre fields and 9847 stars for the thin–thick disc programme during the Pilot Survey, and

an additional 31 365 stars have been observed by the K2–HERMES programme.

We have also intentionally observed 4448 *Tycho-2* stars in 26 fields to correspond with the first *Gaia* data release, with another 6586 stars observed serendipitously in the regular GALAH survey fields. Of these, we are making available analysis results for 10 680 observations of 9860 stars (3801 observations of 3675 targeted stars and 6879 observations of 6185 serendipitous stars) that have

**Figure 15.** Map of the GALAH–TGAS catalogue in right ascension and declination, colour-coded by radial velocity. The solar motion relative to the local standard of rest can be clearly seen.

successfully been processed through our parameter and abundance determination pipeline. A catalogue of stellar parameters, radial velocities, distance moduli and reddening for these successfully analysed stars is presented in this publication, to support broad scientific exploitation of the first *Gaia* data release. As demonstrated above, these parameters look quite robust. We anticipate that they will improve further when we adapt our spectroscopic analysis pipeline to include the stellar distances derived by the TGAS (Michalik et al. 2015) and future *Gaia* data releases. Combining spectroscopic data sets with *Gaia* data serves many important purposes beyond improving spectroscopic analysis. Future GALAH data releases will add elemental abundance information for the stars with the best *Gaia* parallaxes and proper motions, enabling chemodynamic studies in the solar neighbourhood and throughout the Galaxy, and adding kinematic information into chemical tagging.

The target selection and field tiling for GALAH are fixed, and we will continue to follow the same observing rules for the duration of the survey, maintaining our straightforward selection function. Based on Galactic models and our target selection strategy, we anticipate a final data set that is dominated by the thin and thick discs, but despite the small fraction of halo and bulge stars expected (<1 per cent), these data sets will also have significant scientific value. Further details on the data set as observed will be available in Sharma et al. (in preparation).

## ACKNOWLEDGEMENTS

SLM and DBZ acknowledge support from Australian Research Council grants DE140100598 and FT110100743. JPM is supported by a UNSW Vice-Chancellor’s Research Fellowship. KL and SB acknowledge funds from the Alexander von Humboldt Foundation in the framework of the Sofja Kovalevskaja Award endowed by the Federal Ministry of Education and Research as well as funds from the Swedish Research Council (Grant no. 2015-00415\_3) and Marie Skłodowska Curie Actions (Cofund Project INCA 600398). This work was partly supported by the European Union FP7 programme through ERG grant number 320360. This research made use of Astropy, a community-developed core Python package for Astronomy (Astropy Collaboration 2013). This work has made use of data from the European Space Agency (ESA) mission *Gaia* (<http://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC,

<http://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement.
