ABSTRACT

The merging rate of double neutron stars (DNS) has a great impact on many astrophysical issues, including the interpretation of gravitational waves signals, of the short gamma-ray bursts (GRBs), and of the chemical properties of stars in galaxies. Such rate depends on the distribution of the delay times (DDT) of the merging events. In this paper, we derive a theoretical DDT of merging DNS following from the characteristics of the clock controlling their evolution. We show that the shape of the DDT is governed by a few key parameters, primarily the lower limit and the slope of the distribution of the separation of the DNS systems at birth. With a parametric approach, we investigate on the observational constraints on the DDT from the cosmic rate of short GRBs and the europium-to-iron ratio in Milky Way stars, taken as tracer of the products of the explosion. We find that the local rate of DNS merging requires that ~ 1 per cent of neutron stars progenitors live in binary systems which end their evolution as merging DNS within a Hubble time. The redshift distribution of short GRBs does not yet provide a strong constraint on the shape of the DDT, although the best-fitting models have a shallow DDT. The chemical pattern in Milky Way stars requires an additional source of europium besides the products from merging DNS, which weakens the related requirement on the DDT. At present both constraints can be matched with the same DDT for merging DNS.

Key words: gravitational waves – stars: abundances – gamma-ray burst: general – stars: neutron – galaxies: evolution.

1 INTRODUCTION

The detection of gravitational waves in the most recent years has opened a new venue for astrophysics, in particular with respect to the topic of the merging of compact objects. So far, 11 confirmed events of binary black hole merging, and two confirmed binary neutron star merging have been collected (Abbott et al. 2019; The LIGO Scientific Collaboration et al. 2020; Abbott et al. 2020). For more than three decades, the merging of two neutron stars has been proposed to be at the origin of the short gamma-ray bursts (SGRB) phenomenon (Paczynski 1986; Eichler et al. 1989; Narayan, Paczynski & Piran 1992; Li & Paczyński 1998; Tutukov & Fedorova 2007; Giacomazzo et al. 2013). These events have also been proposed as responsible of part of the enrichment of some r-process elements, like europium (Eu, Lattimer et al. 1977; Meyer 1989; Freiburghaus, Rosswog & Thielemann 1999; Rosswog et al. 1999; Korobkin et al. 2012; Hotokezaka et al. 2013). This picture has gained strong credit with the observations of the counterpart of the gravitational waves detection GW170817 (see e.g. Ciolfi 2020), originated from the merging of two neutron stars (Abbott et al. 2017a), in gamma-rays (Abbott et al. 2017c), and X-rays and optical wavelengths (Abbott et al. 2017b). The latter transients correspond to the electromagnetic emission which accompanies an explosive event resulting from the merging of the two neutron stars, often addressed to as *kilonova* (see e.g. Tanvir et al. 2013; Berger 2014). Therefore, the rate of merging of binary neutron stars in stellar systems is a fundamental element to interpret the data measured by gravitational waves detectors, to model the

occurrence of SGRBs in galaxies and as a function of redshift, as well as to model the chemical evolution of galaxies, especially for what concerns those nucleosynthetic products from kilonovae.

In a stellar system, the merging rate of double neutron stars (hereafter DNS) results from the convolution of the star formation history with the distribution of the delay times¹ (hereafter DDT) of the events. If the delay times are short the rate of DNS merging closely follows the star formation rate, similar to the case of core-collapse supernovae (CC-SNe). The fact that some SGRBs have been associated with early type galaxies (Fong & Berger 2013) argues for some events occurring well after star formation has ceased, that is, for a component with long delay times, similar to the case of type Ia supernovae (SNe Ia). In other words, the DDT of DNS merging is likely to be a wide distribution function, including *prompt* as well as *delayed* events. The DDT, which is proportional to the DNS merging rate from one single stellar generation, is a crucial ingredient for modelling the occurrence of kilonovae explosions in galaxies of different types, and, in turn, for calculating the time-scale over which their products are released to the interstellar medium (ISM).

The redshift distribution of SGRBs and their properties (e.g. luminosity, fluence, and duration) have been used to characterize the DDT of DNS merging events in several works (e.g. Guetta & Piran 2006; Virgili et al. 2011; D'Avanzo et al. 2014; Wanderman & Piran 2015). These efforts combine a description of the cosmic star formation history with parametrized functions for the DDT, to construct models and compare them to the data. Often the results

¹The delay time is the time elapsed between the birth of the binary system and its final merging.

indicate a DDT which scales with the inverse of the delay time (see also Ghirlanda et al. 2016).

Abundance and abundance ratios of Milky Way stars can also be used to derive important constraints on the DDT of merging DNS. Models of chemical evolution (Matteucci et al. 2014) including merging DNS as producers of a pure r-process element like Eu have shown that these events can be responsible for the total Eu production in the solar vicinity, but only if the delay time for merging is constant and quite short (1 Myr from the formation of the system), and if the mass range of neutron stars progenitors extends from 9 to 50 M_{\odot} . Alternatively, if both CC-SNe and merging DNS contribute to the Eu production, the data could be reproduced allowing longer delay times for the merging DNS. Côté et al. (2018) pointed out that in order to reproduce the [Eu/Fe] versus [Fe/H] relation in the solar vicinity, which is very similar to that of any α -element relative to Fe, a DDT such as that of SNe Ia would produce results at variance with the observations. They tested time delay distribution functions scaling as $\propto t^{-a}$ (with $a = 1$ and 1.5). Adopting a modified power law for the DDT, and exploring a variety of options, Simonetti et al. (2019) showed that in order to reproduce the observed cosmic rate of SGRBs and to justify the occurrence of the GW170817 event in an early type galaxy, the DDT should be rather shallow, with an average coalescence time of 300–500 Myr. On the other hand, the evolution of [Eu/Fe] versus [Fe/H] abundance ratio in the solar vicinity requires a shorter time-scale for the Eu production, which could be accomplished either adding an early and continuous contribution by CC-SNe, or assuming that the fraction of merging DNS per unit mass of the parent stellar population varies with time, with more events in the past.

The DDT of merging DNS can also be computed numerically with the binary population synthesis (BPS) technique, which takes full advantage of the results of the stellar evolution theory (e.g. Tutukov & Yungelson 1993; Nelemans, Yungelson & Portegies Zwart 2001; Dominik et al. 2012; Mennekens & Vanbeveren 2016; Mapelli et al. 2017; Giacobbo & Mapelli 2018; Eldridge, Stanway & Tang 2019; Tang et al. 2020). The typical evolutionary path leading to the formation of a DNS system which merges within a Hubble time starts with a close binary made of two massive stars, progenitors of a neutron star remnant (Faber & Rasio 2012; Tauris et al. 2017). The primary evolves and upon expansion it may overflow its Roche lobe and lose mass, which may or may not be accreted by the companion. In any case, the primary will eventually explode as an SN leaving behind a neutron star remnant. Upon evolution, the secondary expands and fills its Roche lobe. A common envelope (CE) phase follows, during which the binary system shrinks because of friction. Part of the orbital energy is transferred to the CE which is eventually dispersed in the ISM, leaving behind a system composed of a neutron star and a Helium star companion. During its evolution the Helium star expands and may again fill its Roche lobe, possibly leading to another CE phase, and further shrinking the system. The SN explosion from the secondary will thus leave a close binary neutron star system, which will eventually merge because of angular momentum loss due to the emission of gravitational waves radiation. The DNS formation may however be aborted when either of the two SN explosions occur, as the system may disrupt because of the effect of the SN kick.

The BPS computations start from a population of primordial binaries and follow their evolution through the several mass exchange phases. Many recipes need to be implemented in BPS codes, including those describing the response of the two stars to Roche lobe overflow, the SN kick and its impact on the system (e.g. Bray & Eldridge 2018), the binding energy of the stellar envelope, the efficiency of the CE phase in shrinking the system, the initial–final

mass relation, the radius evolution of the individual components, as well as the dependence on the chemical composition of the stellar evolutionary models. In addition, the distribution of the binaries in mass of the primary, mass ratio, and separation add parameters to the BPS computations. Some of these ingredients are robust, some are founded on empirical data, some are poorly known, for example, the CE efficiency. Meanwhile, the computation of the DDT of merging DNS involves following the evolution of the binaries from an initial separation of several hundreds of R_{\odot} , needed to avoid premature merging, down to a final separation of a few R_{\odot} or less, in order to ensure merging within a Hubble time, through an intermediate phase in which the separation could reach a few thousands of R_{\odot} (see Belczynski et al. 2018). This requires an accurate description of the various mass exchange phases. Besides, as noticed in Chruslinska (2019), only a small fraction of the theoretical binary population ends up in DNS merging within a Hubble time, some systems merging before the formation of the two neutron stars, some ending up with too long coalescence time-scales, some other because of disruption when either of the two SNe explode. Therefore, the description of the SN kick and of the system response to it strongly impact on the BPS results (see Giacobbo & Mapelli 2018). The local rates of kilonovae predicted by BPS computations and reported in Chruslinska (2019) show a large variance, likely due to different recipes implemented in the codes (Tang et al. 2020).

In this paper, we present an alternative approach for determining the DDT of DNS mergers, similar to that developed in Greggio (2005) for the rate of SNe Ia, that is, focusing on the properties of the clock which governs the merging events. Rather than following the evolution of individual systems, we look at the parameters which predominantly control the delay time and derive the DDT from the distribution of these parameters. Based on this approach, we elaborate parametrized models for the shape of the DDT which results from the properties of the clock; then we derive constraints on the shape of the DDT by comparing the redshift distribution of SGRBs to models obtained combining the theoretical DDTs with the cosmic star formation history in Madau & Dickinson (2014). The local rate of kilonovae estimated by Abbott et al. (2020) is used to calibrate the models, which allows us to evaluate the efficiency of kilonova production from a stellar population. Finally, we test the models on their ability to account for the chemical trend of Eu and Iron abundances in the Milky Way. A similar exercise was presented in Simonetti et al. (2019) where we adopted a shape for the DDT based on generic arguments in accordance to the results in Greggio (2005) for SNe Ia. Here, we revisit the problem with a more rigorous determination of the DDT, exploring the effect of the distribution of the binary masses, eccentricity and separations. Our results include a variety of DDTs which cover a wide parameter space. We anticipate that the shape of the DDT turns out to crucially depend on the distribution of the separations of the binary neutron stars at birth and on its lower boundary. This offers a key to appraise the results of BPS codes with respect to the various recipes implemented to follow the close binaries evolution.

As a note of caution we remark that the models presented here are applicable only to binaries which evolve in isolation, while merging DNS can also be produced by dynamical processes which take place in dense environments, for example, globular clusters (Lee, Ramirez-Ruiz & van de Ven 2010). The contribution of the dynamical to the total rate of merging DNS events is unclear: according to Belczynski et al. (2018), in old stellar populations the current rate of DNS merging from the dynamical channel is ~ 150 times lower than the rate from isolated binaries. On the other hand, models for the cosmic rate of DNS mergers by Santoliquido et al. (2020) show that the

Figure 1. The mass-dependent term in equation (2) is plotted as a function of the total mass of the binary, for m_1 and m_2 ($\leq m_1$) ranging from 1.1 to $2 M_\odot$. Larger symbols refer to higher values of the primary mass. The solid line represents a good approximation to this term.

dynamical channel contributes $\sim 1/3$ of all the local events. Our arguments are based on a delay time which does not include the time taken by the dynamical interaction to form the DNS system; therefore they are relevant for the contribution to the merging DNS events from binaries which evolve unperturbed by the environment.

The paper is organized as follows: in Section 2, we describe the properties of the coalescence time-scales, in Section 3 we show our models for their distribution, illustrating the dependence on the distribution of the total mass, of the separation and eccentricity of the DNS systems at birth. In Section 4, we derive model distributions of the total delay times, which include the time necessary to produce the DNS system. In Section 5, we discuss the constraints on the DDT from the SGRBs redshift distribution and derive an estimate for the efficiency of DNS system production from a stellar population needed to account for the local rate of kilonovae. In Section 6, we compare chemical evolution models constructed with our model DDTs to the Eu and Fe trend in Milky Way stars; and in Section 7 we summarize our results and draw some conclusions.

2 THE DELAY TIME

For a binary system which evolves in isolation the time elapsed between the formation of the primordial system and the final merging is the sum of the evolutionary lifetime of the secondary component (τ_n , hereafter referred to as the nuclear delay) and the time taken by the gravitational wave radiation to bring the components into contact (τ_{GW} , hereafter referred to as GWR delay). The first time-scale is a function of the initial mass of the star (m) and of the chemical composition. For the sake of simplicity, we neglect the dependence on metallicity, and adopt the relation

$$\log m = 0.49(\log \tau_n)^2 - 7.80 \log \tau_n + 31.88 \quad (1)$$

with mass in solar units and time years. Equation (1) was derived from fitting the lifetimes of the neutron stars progenitors in the Limongi & Chieffi (2006) models, complemented with the Bertelli et al. (2009) tracks, with solar metallicity. We notice that, due to interaction, in

Figure 2. The GWR delay as from equation (3), as a function of the eccentricity, for different values of the separation of the DNS system at formation (A) labelled on the solid lines (values are in units of R_\odot). Solid lines adopt a total mass of the binary of $3 M_\odot$, while the shaded areas show the range of τ_{GW} for M_{DN} varying between 2.2 and $4 M_\odot$ at fixed separation and eccentricity. The dashed line is drawn at $\tau_{\text{GW}} = 13.5$ Gyr.

a close binary the masses of the components may change, leading to a modification of the evolutionary lifetimes. For example, the mass of the secondary may increase leading to a shortening of the nuclear delay with respect to equation (1). In our simple approach, we also neglect the lifetime of the CE phase which is likely very short compared to other time-scales involved (e.g. Igoshev, Perets & Michaely 2020). In general, equation (1), which is appropriate for stars evolving in isolation, represents an approximation to the evolutionary lifetime of the secondary star in a close binary; yet it accounts for a basic trend of this component of the delay time related to the different masses of the secondaries in the progenitor systems.

The time delay due to the action of the gravitational waves radiation can be expressed as (Peters 1964):

$$\tau_{\text{GW}} = \frac{0.15 A^4}{m_1 m_2 (m_1 + m_2)} \times (1 - e^2)^{7/2} \text{Gyr} \quad (2)$$

where A , m_1 , and m_2 are respectively the separation and the masses of the components (in solar units), and e is the eccentricity of the binary, all parameters evaluated at formation of the DNS system. Fig. 1 shows the mass dependent factor in equation (2) as a function of the total mass of the binary ($M_{\text{DN}} = m_1 + m_2$), assuming that the mass of a neutron star varies between 1.1 and $2 M_\odot$, a range suggested by observational determinations (Martínez et al. 2015; Antoniadis et al. 2013). It appears that the mass dependent factor can be well represented with the expression $y = 0.25 \times M_{\text{DN}}^3$; equation (2) can then be approximated as

$$\tau_{\text{GW}} = \frac{0.6 A^4}{M_{\text{DN}}^3} \times (1 - e^2)^{7/2} \text{Gyr}. \quad (3)$$

Fig. 2 shows the GWR delay as a function of the eccentricity for different values of the separation and total mass of the binary. This figure illustrates the main characteristics of the GWR clock:

(i) τ_{GW} is sensitive to all three parameters and it decreases as the eccentricity and the binary mass increase, and as the separation decreases;

(ii) although a value of τ_{GW} corresponds to a variety of combinations of the parameters, there is a maximum delay achievable with a given value of the separation. In other words, all close systems merge on a short time-scale, while only wide systems can merge on a long τ_{GW} ;

(iii) most of the relevant parameter space is limited to the range $A \lesssim 10 R_{\odot}$, since wider systems can contribute to merging within a Hubble time only if born with very high eccentricities. Indeed, the range of eccentricities leading to merging time-scales shorter than the Hubble time rapidly shrinks as A increases beyond $8 R_{\odot}$.

To summarize: (i) the great majority of the systems merging within a Hubble time have initial separations in a small range, (ii) the total mass of the DNS system also varies within a small range, and (iii) for any (A, M_{DN}) combination, a wide range of eccentricities yields the same value of τ_{GW} . To the aim of describing the general properties of the distribution of the GWR delays, it appears then appropriate to adopt continuous parametrized expressions for the distributions of (A, M_{DN}, e) , to be folded with equation (3). In this way, we aim at characterizing the distribution of τ_{GW} and its dependence on the various astrophysical parameters, identifying the most important ones.

3 MONTECARLO SIMULATIONS FOR THE DISTRIBUTION OF THE GWR DELAYS

We adopt power-law distributions for the separation, binary mass, and eccentricity:

$$\begin{cases} f(A) \propto A^{\beta} \\ f(M_{\text{DN}}) \propto M_{\text{DN}}^{\gamma} \\ f(e) \propto e^{\rho}. \end{cases} \quad (4)$$

The choice for the distribution of A finds some support from the numerical results of BPS computations: for example, in Giacobbo & Mapelli (2018) the distributions of the separations of DNS systems which merge within a Hubble time can be described as a power law with exponent $\simeq -1$, and a downturn at separations below $\sim 1 R_{\odot}$. Also Belczynski et al. (2018) find a power-law distribution for the separations of the DNS systems at formation, albeit with steeper exponent, $\simeq -3$, and no evident downturn at the smallest separations. The adoption of power-law distributions for M_{DN} and e is more arbitrary, but will turn out relatively unimportant for the slope of the DDT.

3.1 Results for independent variables

Fig. 3 shows the distribution of the GWR delays under different options for the exponents (β, γ, ρ) , in the hypothesis that A, M_{DN} , and e are independent variables. We consider β varying between -1 and -3 on the basis of the results of BPS realizations mentioned above, while the tested values of the parameters γ and ρ are meant to explore the general response of the distribution of τ_{GW} to the distributions of binary mass and eccentricity. The two cases $\gamma = 0$ and -10 show the effect of going from a flat distribution of M_{DN} to a case in which the great majority of systems are found at the low-mass end; the three values of ρ depict the effect of varying the distribution of eccentricities from a function favouring low ($\rho = -0.5$) to one favouring high ($\rho = 1$) values of e .

At delays longer than 0.1 Myr, the distribution of τ_{GW} is very well described by a power law with an exponent $s \simeq -1, -1.25$, and

-1.5 , respectively for $\beta = -1, -2$, and -3 , while the parameters γ and ρ have a negligible effect. In Appendix A, we show that, under some simplifications, the distribution of τ_{GW} can be derived analytically, and results in a power law with exponent $s = 0.25 \times \beta - 0.75$ modified at short delay times. In fact, the lower limit adopted for the separation A implies a dearth of fast merging systems, causing a flattening of the distribution at short τ_{GW} . The effect is amplified when lower values of γ , which disfavour massive systems, are assumed. Similarly, the flattening is more pronounced for lower values for ρ , which imply a larger fraction of low eccentricity systems.

These patterns appear well visible in the cumulative distributions of the GWR delays (bottom panels). For $\beta = -3$, 90 per cent of the systems merge within ~ 1 Myr from the formation of the second neutron star, while for $\beta = -1$ only ~ 70 per cent of the systems merge within a Hubble time. Therefore, the time-scale for the release of nucleosynthetic products from kilonovae is extremely sensitive to this parameter. The cumulative distributions also emphasize the dependence of the results on ρ and γ , with a larger fraction of systems at short τ_{GW} obtained with the higher values of ρ and γ .

3.2 Effect of the supernova kick

As mentioned above, the distributions in Fig. 3 have been computed assuming that A, M_{DN} and e are independent variables. However, in real DNS systems one may expect that the larger separations are coupled to higher eccentricities as a consequence of the SN kick. The effect on the orbit of the DNS system induced by the kick due to an asymmetric explosion of the second SN has been studied in detail by Kalogera (1996) and more recently by Andrews & Zezas (2019). In the latter paper, the authors perform simulations of binaries formed by a neutron star plus a massive Helium star which undergo a kick when the Helium star explodes. The simulations are computed for a distribution of SN kicks, Helium star masses and separations of the system. The results show that the ratio between the final and the initial separation (A_f/A_i) and the eccentricity are not uniformly distributed, but rather cluster around two loci: $A_f/A_i = (1 \pm e)^{-1}$. Thus, it appears that the effect of the kick is that of promoting a relation between the separation and eccentricity of DNS systems: some on the branch $A_f/A_i = (1 + e)^{-1}$ (branch 1) characterized by a general shrinking of a factor up to 2, others on the branch $A_f/A_i = (1 - e)^{-1}$ (branch 2), which can turn out very wide, but at the same time with large eccentricities. Since the GWR delay is very sensitive to both the separation and the eccentricity it is important to explore the effect of these relations. Therefore, we performed another set of Monte Carlo simulations in which we extract pairs of values of (A_i, e) , to which we associate a value for the separation to be used in equation (3) of $A_f = A_i/(1 \pm e)$, the two branches randomly represented in equal proportions. The parameters (A_i, e) are considered independent and follow the power law distributions with exponents β and ρ , respectively. The results of this set of Monte Carlo extractions are shown in Fig. 4. Systems which belong to branch 1 end up with a relatively short τ_{GW} due to the smaller separation, while systems which belong to branch 2 have a long τ_{GW} because of the larger A_f . In our experiment the second effect prevails so that the overall distribution becomes more populated at the long GWR time-scales compared to what obtained when the variables are assumed independent (see grey lines in Fig. 4). The differential distributions still appear well represented by a power law with slope $s = 0.25\beta - 0.75$ at $\tau_{\text{GW}} \gtrsim 1$ Myr, but the flattening of the distributions at early times is more pronounced, and more systems merge on longer GWR delays. The cumulative distributions (bottom panel) better illustrate the change, with 50 per cent of the systems merging within 1 Gyr if $\beta = -1$. Steeper distributions of A_i yield much shorter time-

Figure 3. Differential (top) and cumulative (bottom) distributions of the GWR delays from Monte Carlo simulations, assuming that (A, M_{DN}, e) vary independently in $0.2 \leq A/R_{\odot} \leq 30$, $2.2 \leq M_{\text{DN}}/M_{\odot} \leq 4$, and $0 \leq e < 1$. The simulations include (6000, 500, 1000) values of respectively (A, M_{DN}, e) for a total of 3×10^9 random extractions. Left-, central, and right-hand panels show the results obtained with $\beta = -1, -2$, and -3 , respectively. The colour and line type encode the parameter ρ , while the line thickness encodes the parameter γ , as labelled in the left-hand panels. The arrows in the top panels show power laws with slopes of $s = -1, -1.25, -1.5$ from left to right.

scales, but still longer than those obtained for the case of independent variables, for the same value of β . It also appears that in this set of simulations the relation between e and A_i/A_i reduces the sensitivity of the distributions on the γ and ρ parameters, the cumulative curves running close to each other, especially at $\tau_{\text{GW}} \gtrsim 0.1$ Myr.

Given the sensitivity of the GWR delay to the separation, the limits on this parameter impact on the resulting distributions. We have then performed more simulations varying the minimum ($A_{i, \text{min}}$) and maximum ($A_{i, \text{max}}$) separation of the binary systems before the second SN explosion. In these simulations we adopt the scheme which describes the effect of the SN kick on the orbit which seems more akin to actual astrophysical situations. Fig. 5 shows the effect of varying $A_{i, \text{min}}$, while varying $A_{i, \text{max}}$ has a weak impact, as we show in Appendix A. The differential distributions (top panels) still appear to follow two regimes: a power law with slope $s = 0.25\beta - 0.75$ at relatively long GWR delays, and a flatter relation at short delays. The value of τ_{GW} at which this transition occurs gets shorter and shorter as $A_{i, \text{min}}$ decreases, because of the higher number of systems with small values of A_i . For the same reason, as $A_{i, \text{min}}$ decreases, the fraction of early merging increases. For $\beta = -1$, the fraction of systems merging within 1 Myr varies from ~ 0.05 to ~ 0.3 as $A_{i, \text{min}}$ decreases from 1 to $0.1 R_{\odot}$. As the distribution of the separations steepens (β decreases)

more and more systems are born with small separations and their merging time-scales become shorter and shorter. For $\beta = -3$, the fraction of systems merging within 1 Myr goes from ~ 15 per cent to ~ 90 per cent as $A_{i, \text{min}}$ decreases from 1 to $0.1 R_{\odot}$. Notice however that these figures result from having described the distribution of the separations as a pure power law, which maximizes the number of systems at the low A_i values by construction.

3.3 The distribution of the GWR delays

The results of the simulations can be summarized as follows:

(i) The distribution of the GWR delays is mostly sensitive to the distribution of the separations of the binary systems when the second neutron star is formed. Describing the latter with a power law with exponent β , the distribution of the GWR delays is also a power law with exponent $s = -0.75 + 0.25 \times \beta$ for delays longer than some characteristic $\tau_{\text{GW}} (\lesssim 10 \text{ Myr})$.

(ii) The minimum value of the separation is a crucial parameter for the fraction of systems with short merging time-scales; its impact depends on how steep the distribution of A_i is; in the extreme combination $A_{i, \text{min}} = 0.05 R_{\odot}$ and $\beta = -3$ we find that all DNS systems merge within 1 Myr from their formation.

Figure 4. The same as in Fig. 3 but for Monte Carlo simulations which incorporate a description on the effect of the SN kick on the orbital parameters (see the text). The simulations include 10^6 values of (A_i, e) pairs and 1000 values of M_{DN} , for a total of 10^9 random extractions. In grey, we plot the results of the Monte Carlo simulations shown in Fig. 3. The distributions in the top panels have been scaled to the same total number of extractions of 10^9 .

(iii) The dependence of the distribution of the GWR delays on the distribution of the other variables, (M_{DN} and e) is less pronounced. However, in general, the larger the fraction of massive and/or eccentric binaries, the larger the fraction of systems merging on a short time-scale.

Although the distributions of the three variables (A , M_{DN} , e) will not be pure power laws, we believe that our simulations explore a sufficiently wide parameter space to derive crucial characteristics of the distribution of the GWR delays. Concerning the value of the $A_{i, \text{min}}$ parameter, we remark that the radius of Helium stars progenitors of a neutron star ranges between ~ 0.3 and $1 R_{\odot}$ (Woosley 2019) during the central Helium-burning phase. Systems with separations smaller than several tenths of R_{\odot} are likely to undergo mass exchange before Helium ignition, thereby avoiding the successive nuclear burnings which lead to the SN explosion. For systems in which the Helium star component completes core Helium burning inside its Roche lobe, further orbital shrinking could however occur during the evolution after central Helium exhaustion, when the Helium star expands. Models by Laplace et al. (2020) show that the final separation of the system could be as low as $\sim 0.07 R_{\odot}$. Therefore we also computed models adopting $A_{i, \text{min}} = 0.05 R_{\odot}$. It appears however very unlikely that the distribution of the separations of DNS systems is a power

law all the way down to such a small value; nevertheless this extreme case allows us to check the results of chemical evolution models when the nucleosynthetic contribution from kilonovae occurs on an extremely short time-scale.

4 THE DISTRIBUTION OF THE TOTAL DELAY TIME

As anticipated in Section 2, for a DNS system evolving in isolation, the total delay time is the sum of the evolutionary lifetime of the secondary component with the GWR delay. In this section, we derive the differential distribution of the total delay times of merging DNS systems, starting from the cumulative distribution.²

The contribution to the systems with total delay shorter than τ_d from systems with nuclear delay between τ_n and $\tau_n + d\tau_n$ is:

$$dn(\tau_d) = n(\tau_n) \times g(\tau_n, \tau_d) d\tau_n \quad (5)$$

where $n(\tau_n) d\tau_n$ is the number of binaries with nuclear delay between τ_n and $\tau_n + d\tau_n$, and $g(\tau_n, \tau_d)$ is the fraction of them with GWR delay

²We follow this approach because τ_n and τ_{GW} are not independent variables, both being related to the mass of the secondary component of the system.

Figure 5. Differential (top) and cumulative (bottom) distributions of the GWR delays from Monte Carlo extractions for different choices of the minimum separation of the binary system prior to the second SN explosion: $A_{i,\min}/R_{\odot} = 0.1, 0.2, 0.5,$ and 1 , plotted respectively as green (solid), blue (dashed), red (dotted–dashed), and black (dotted) lines. All simulations adopt the same maximum value for the separation $A_{i,\max} = 50 R_{\odot}$. Each simulation comprises 10^6 values of (A_i, e) pairs and 1000 values of M_{DN} , for a total of 10^9 random extractions, and includes a description of the effect of the SN kick. For each value of A_i , we plot six lines, each corresponding to a choice for the parameters of the distribution of M_{DN} ($\gamma = -10, 0$) and of the eccentricity ($\rho = -0.5, 0, 1$). The left-hand, central, and right-hand panels show the results for different slopes of the distribution of separations A_i as labelled in the bottom left panel.

shorter than $(\tau_d - \tau_n)$. For each nuclear delay, $g(\tau_n, \tau_d)$ is the value of the cumulative distribution of τ_{GW} presented in the previous section, read off at the appropriate $\tau_{\text{GW}} = \tau_d - \tau_n$.

Summing on the relevant range of τ_n we derive the total number of systems with delay shorter than τ_d as:

$$F(< \tau_d) = \int_{\tau_{n,i}}^{\min(\tau_d, \tau_{n,x})} n(\tau_n) g(\tau_d, \tau_n) d\tau_n \quad (6)$$

where $\tau_{n,i}$ and $\tau_{n,x}$ bracket the range of nuclear delays which contribute to the kilonova explosions, that is, the evolutionary lifetimes of their progenitors.

4.1 The distribution of the nuclear delay

The distribution of the nuclear delays can be derived as (see e.g. Greggio & Renzini 2011):

$$n(\tau_n) \propto n(m_2) \left| \frac{dm_2}{d\tau_n} \right| \quad (7)$$

where m_2 is the mass of the secondary star with evolutionary lifetime equal to τ_n . The distribution function of the secondary masses in the systems of interest can be derived from (see Greggio 2005):

$$n(m_2) \propto \int_{m_{1,\min}}^{m_{1,\max}} n(m_1) f(q) \frac{dm_1}{m_1} \quad (8)$$

where m_1 is the mass of the primary, $n(m_1)$ is its distribution function, q is the mass ratio (m_2/m_1), and $m_{1,\min}$ and $m_{1,\max}$ bracket the range of primary masses of interest. Assuming that the mass of neutron star progenitors ranges between 9 and $50 M_{\odot}$, we have that $m_{1,\min}/M_{\odot} = \max(9, m_2)$ and $m_{1,\max}/M_{\odot} = 50$.

Fig. 6 shows the distribution function of the nuclear delays computed with equations (1), (7), and (8) for different distributions of the primary masses and mass ratios (see the caption). The function $n(\tau_n)$ is defined between a minimum ($\simeq 4.5$ Myr) and a maximum ($\simeq 32$ Myr) value of the nuclear delay, respectively the evolutionary lifetimes of the maximum and minimum mass of neutron star progenitors adopted. Within these limits, as τ_n increases, the distribution first increases, due to the effect of the initial mass function (IMF) which provides more and more systems with smaller m_2 . This effect

Figure 6. The distribution of evolutionary lifetimes of the secondary in DNS system progenitors for three choices of the distribution of the primary masses and mass ratios. Black solid line: $n(m_1) \propto m^{-2.35}$, $f(q) \propto q$ (the combination adopted here); red, long dashed line: $n(m_1) \propto m^{-2.3}$, $f(q) \propto q^{-0.1}$ (the combination in Giacobbo & Mapelli 2018) and blue, short dashed line: $n(m_1) \propto m^{-2.6}$, $f(q) \propto q^0$ (a steep IMF combined with a flat distribution of the mass ratios).

is countered by the decrease of the rate of change of the secondary mass (i.e. the m_2 factor in equation 7), so that the function shows a wide maximum and then decreases. Note that the adopted mass limits for the neutron star progenitors are not critical for the shape of the distribution of the nuclear delays. The distribution $n(\tau_n)$ appears mildly affected by the choice of $n(m_1)$ and $f(q)$; in the following, we adopt a Salpeter IMF for the primary masses and a distribution of the mass ratios which favours the high values of q ($f(q) \propto q$).

4.2 The final DDT

With these ingredients we have computed the distribution of the total delay time of kilonova explosions (f_{kn}) by first deriving the cumulative distribution from equation (6) and then computing its derivative with respect to the delay time:

$$f_{\text{kn}}(\tau_d) = \frac{d}{d\tau_d} F(< \tau_d). \quad (9)$$

Fig. 7 shows the resulting DDT, normalized to unity over the range $0 \leq \tau_d \leq 13.5$ Gyr. All distributions show a strong early peak followed by a decline which can be well described with a power law. The peak is populated by systems merging soon after the formation of the neutron star from the secondary component of the binary. No merging occurs earlier than $\tau_d \simeq 4.5$ Myr, because this is the evolutionary lifetime of the most massive secondary considered here as neutron star progenitor. In the range of delay times between 4.5 and 32 Myr the requirement $\tau_d = \tau_n + \tau_{\text{GW}}$ is met with an increasing range of values of both τ_n and τ_{GW} . The evolutionary lifetime of the least massive neutron star progenitor considered here is $\simeq 32$ Myr: mergings at delay times longer than this are achieved only with $\tau_d - 32 \lesssim \tau_{\text{GW}}/\text{Myr} \lesssim \tau_d - 4.5$, reflecting the constraint on the nuclear lifetimes of the kilonova progenitors. The hard limit on τ_n causes the discontinuity at 32 Myr in the delay times distribution; beyond this limit f_{kn} scales essentially as the distribution of the GWR delays. The same argument was elaborated in Greggio (2005) for the DDT

of SNe Ia. We remark that the DDT is proportional to the event rate for a single burst of star formation. Similar to the case of SNe Ia, the rate of DNS merging per unit mass will be large in young and low in old stellar systems, the actual value being the result of the DDT weighted by the star formation history of the system.

Fig. 7 shows that the DDT depends mostly on the parameters β and $A_{i,\text{min}}$ which characterize the distribution of the separations of the binaries when the second SN explodes. The peak at short delay times is stronger for distributions which are more populated at low values of A_i either because of a steeper β , or because of a smaller limit $A_{i,\text{min}}$, or both. The dependence on the parameters γ and ρ which characterize the distribution of binary masses and eccentricities is small, especially so when the distribution of the separations is relatively flat. In the upper panels of Fig. 7, we also plot an arrow which represents a power law with exponent $s = -0.75 + 0.25\beta$. In most cases the DDT decline follows this power law at delay times longer than $\simeq 0.1$ Gyr, but for some combinations of the parameters this regime sets at a later epoch. Actually, our adopted scheme to describe the effect of the SN kick impacts on the distribution of the coalescence delays enhancing the fraction of systems with late merging time-scales (see Fig. 4). The effect is stronger for lower values of β and higher values of ρ .

In the lower panels of Fig. 7 the vertical line is drawn at $\tau_d = 32$ Myr, which can be taken as a partition between *prompt* and *delayed* events: *prompt* kilonovae release their products on a time-scale close to that of their progenitors, *delayed* kilonovae do so after their SN progenitors have polluted the ISM. The fraction of *prompt* and *delayed* events impacts on the chemical evolution of the system by leaving their imprint on the abundance ratios. The fraction of *prompt* events is very sensitive to the parameters β and $A_{i,\text{min}}$, but notice that as $A_{i,\text{min}}$ decreases this dependence greatly mitigates, and the lower limit to the distribution of A_i becomes unimportant. For $\beta = -3$ almost all systems merge within 32 Myr for A_i smaller than $0.2 R_\odot$. Conversely, a flat distribution of the separations of DNS system and/or a large lower limit $A_{i,\text{min}}$ imply a late pollution from kilonovae with respect to that of their SNe predecessors.

5 THE COSMIC RATE OF MERGING DNS AND AVERAGE EFFICIENCY OF KILONOVAE PRODUCTION

In order to compute the evolution of the rate of merging neutron stars in stellar systems, we need to estimate the efficiency of production of these events by a stellar population, or the number of merging neutron stars from a stellar population of unitary mass (k_{kn}). To evaluate this quantity, we consider the cosmic rate of SGRBs, as well as the rate of kilonovae estimated by Abbott et al. (2020). The rate of merging at epoch t_0 in a system experiencing a star formation history $\psi(t)$ is given by:

$$R_{\text{kn}}(t_0) = \int_0^{t_0} k_{\text{kn}} \psi(t - \tau_d) f_{\text{kn}}(\tau_d) d\tau_d \quad (10)$$

where f_{kn} is the DDT of merging DNS, and the integration extends over all the successive stellar generations occurred in the system. The efficiency k_{kn} could well depend on time, for example, because of IMF variations, and/or because of the metallicity evolution which may impact on the paths of close binary evolution, as well as on the distribution of initial binary parameters. We take a simplified view neglecting the potential variations of k_{kn} , and proceed evaluating an average value of this efficiency which describes the observed cosmic rates.

Figure 7. Differential (top) and cumulative (bottom) distributions of the total delay times of kilonova explosions for different distributions of the separations, DNS total masses and eccentricity, in the same fashion as in Fig. 5. The arrows in the top panels show power laws with slope of $s = -1, -1.25,$ and -1.5 from left to right. The vertical line in the bottom panels is drawn at a delay time of 32 Myr, that is, the evolutionary lifetime of the least massive neutron star progenitor adopted here.

The DDTs presented in the previous section have been normalized to 1 in the range of delay times $0 \leq \tau_d \leq 13.5$ Gyr. Therefore, equation (10) becomes

$$R_{\text{kn}}(13.5) = k_{\text{kn}} \times \langle \psi \rangle \quad (11)$$

where the last term is the average star formation rate in the system over the last 13.5 Gyr. If ψ is a mild function of time, the last term can be estimated as the ratio between the stellar mass in the considered system and the Hubble time. Equation (11) yields a handy way to estimate the typical efficiency of the evolutionary channel providing merging DNS systems within a Hubble time, which is needed to meet the observed rate of such events. To some extent, this is applicable to the cosmic star formation history, and to stellar populations in late-type galaxies, since their star formation rate is a mild function of time. The efficiency k_{kn} is normalized to the total (initial) mass of a stellar population, and can be expressed as the product of the number of neutron star progenitors per unit mass (k_{α}) and the fraction of them members of binary systems which merge within a Hubble time (α_{MNS}): $k_{\text{kn}} = k_{\alpha} \times \alpha_{\text{MNS}}$. This notation is convenient for the computation of chemical evolution models.

To evaluate k_{kn} we fit the redshift distribution of SGRBs with models obtained from equation (10) adopting the cosmic star formation

rate by Madau & Dickinson (2014)

$$\psi(z) = \frac{0.015(1+z)^{2.7}}{1 + ((1+z)/2.9)^{5.6}} M_{\odot} \text{Mpc}^{-3} \text{yr}^{-1} \quad (12)$$

and our DDTs described in the previous section. The relation between redshift and look-back time adopted is that of the Λ -cold dark matter cosmological model using the parameters found by Bennett et al. (2014) (i.e. $H_0 = 69.6 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.286$ and $\Omega_{\Lambda} = 0.714$). As observational constraint we select the two curves (models *a* and *c*) proposed by Ghirlanda et al. (2016). These authors choose the following functional form for the redshift distribution of all events:

$$\psi_{\text{SGRB}}(z) = \psi_{\text{SGRB}}(z=0) \times \frac{1 + p_1 z}{1 + (z/z_p)^{p_2}} \quad (13)$$

and find the parameters which best fit a variety of observational data, including the observed redshift distribution and energetic properties of the SGRBs. These parameters turn out of $(p_1, p_2, z_p) = (2.8, 3.5, 2.3)$ and $(3.1, 3.6, 2.5)$, respectively for models *a* and *c*. Other options for the redshift distribution of SGRBs can be found in the literature (e.g. Zhang & Wang 2018), but require a DDT poor of prompt events, which is difficult to reconcile with the fact that

Figure 8. The redshift distribution of SGRBs as in curves *a* (upper panels) and *c* (lower panels) in Ghirlanda et al. (2016, dashed black lines) compared to the best-fitting models obtained convolving the cosmic star formation history with selected DDT distributions (coloured lines). Blue, green, and red lines show the models computed with $\beta = -1, -2$, and -3 , respectively. Left-hand (right) panels show models which adopt $A_{i, \min} = 0.1$ ($1 R_{\odot}$). For each combination of the $(\beta, A_{i, \min})$ parameters, we plot with dotted lines all the models computed with the different values of ρ and γ and highlight the best fitting of them with the solid line. Notice that the dependence of the models on the ρ and γ parameters is virtually absent when $A_{i, \min} = 0.1 R_{\odot}$, while for $A_{i, \min} = 1 R_{\odot}$, the distribution of binary masses and eccentricity affect the fitted models.

neutron stars are produced by massive stars which have very short evolutionary lifetimes (see e.g. Simonetti et al. 2019). We obtain the redshift distribution in natural units (events per yr per Gpc^3) by adopting a value of $\psi_{\text{SGRB}}(z=0)$ equal to the local rate of merging neutron stars estimated by Abbott et al. (2020). Notice that this value is compatible with the estimates of the local rate of SGRBs found in the literature (Coward et al. 2012; Petrillo, Dietz & Cavaglia 2013; Fong et al. 2015) within the (large) uncertainties. To find the best-fitting value of the k_{kn} parameter we minimize the distance between the constraining curves and the models in $0 \leq z \leq 2$, which is the redshift range covered by events in the (Ghirlanda et al. 2016) sample.

Fig. 8 shows the results of our fitting procedure using DDTs with the three values of β and two extreme values for the minimum separation of the DNS systems at birth. The combination ($\beta = -3$ and $A_{i, \min} = 0.1$), shown in red on the left-and panels of Fig. 8, favours prompt mergings; the combination ($\beta = -1$ and $A_{i, \min} = 1$), shown in blue on the right-hand panels of Fig. 8, favours mergings at late epochs. In spite of the very different values of the astrophysical parameters characterizing the chosen DDTs, all plotted models yield an acceptable representation of the empirical curves, considering that the latter are not directly measured rates, but rather the result of a fitting procedure applied to observational data, which brings along some uncertainty beyond what indicated with the two solutions *a* and *c*. Models with a small value of $A_{i, \min}$ are characterized by a relatively steep rise of the rate as the redshift increases from $z = 0$ to the peak at $z = 2$, followed by a milder decrease towards higher redshift, while models with $A_{i, \min} = 1 R_{\odot}$ show the opposite trend. Since the empirical redshift distribution is not well constrained at redshifts larger than the peak, it is not possible to draw conclusions from this comparison. It seems however that models with $\beta = -1$ (in blue) better describe the empirical curves in all cases, except for the case plotted in the lower right panel, where curve *c* appears to require a steeper distribution of the separations to compensate for

the relatively large $A_{i, \min} (= 1 R_{\odot})$. Formally, the minimum distance between models and empirical curves *a* and *c*, in the range $0 \leq z \leq 2$, is obtained respectively for the combinations $(A_{i, \min}/R_{\odot}, \beta, \rho, \gamma) = (1, -1, 1, 0)$ and $(0.1, -1, -0.5, 0)$.

From the redshift distribution of the SGRBs, we derive an indication in favour of a DDT with a sizable component at long delay times, but the constraining power of this kind of comparison is very limited, because of the shape of the cosmic star formation rate which accommodates stellar populations with a wide range of ages. On the other hand, this property allows us to derive an estimate for the efficiency k_{kn} which is virtually insensitive to the DDT. We find $k_{\text{kn}} = (6.5 \pm 0.4) \times 10^{-5} M_{\odot}^{-1}$ for all the models fitted to the (Ghirlanda et al. 2016) curves *a*. Fitting the redshift distribution to curve *c* leads to a very close value of $k_{\text{kn}} = (7.3 \pm 0.4) \times 10^{-5} M_{\odot}^{-1}$. We acknowledge that these values rest on observational determinations which are affected by a large uncertainty, and that the factor of ~ 10 uncertainty on the local rate of kilonovae (Abbott et al. 2020) implies the same uncertainty of k_{kn} . We also acknowledge that the approximations introduced to determine k_{kn} weaken its reliability; nevertheless we regard our result as robust, since it is derived under a wide variety of possibilities for the DDT. The cosmic star formation history adopted for the fit assumes a Salpeter IMF, with $k_{\alpha} = 0.006 M_{\odot}^{-1}$ stars with mass between 9 and $50 M_{\odot}$; therefore the measured cosmic rate of merging neutron stars requires that, in a single stellar population, $\simeq 1$ per cent of neutron star progenitors should be found in binary systems which merge within a Hubble time.

6 THE CHEMICAL EVOLUTION OF THE MILKY WAY

We now consider the constraints on the DDT of merging DNS that can be derived from the chemical properties of Milky Way

stars. As mentioned in the Introduction, this can be achieved by comparing models for the trend of the [Eu/Fe] abundance ratio with increasing [Fe/H] to corresponding observations. Eu is a pure r -process element and is produced via explosive nucleosynthesis in neutron-rich environments. This makes merging neutron stars a very likely site for Eu production. Some Eu may also be synthesized in CC SNe (Argast et al. 2004), and in rarer, more exotic explosions of very massive stars, that is, collapsars (Winteler et al. 2012; Siegel, Barnes & Metzger 2019).

6.1 The model

The chemical evolution model employed in this work is the classical two-infall model of Chiappini, Matteucci & Gratton (1997), described in detail in, for example, Matteucci (2012), which assumes that the Galaxy formed out of two main gas infall episodes, one giving rise to the halo plus thick disc and the other to the thin disc. The computations follow the time evolution of the gas abundances of 31 chemical elements (from H to Eu), by solving the equations:

$$\frac{dG_i(t)}{dt} = -\Psi(t) X_i(t) + R_i(t) + X_{i,0} A(t), \quad (14)$$

written for all the i chemical species. For each element, G_i is the surface density in the gas, normalized to the final total surface mass density (gas plus stars), X_i is its abundance in the gas, and R_i is the rate at which the element is given back to the ISM by winds or stellar explosions. The first term, i.e. the product between the star formation rate $\Psi(t)$ and X_i , describes the rate at which the element i is subtracted from the gas due to star formation, while the last term describes the infall of gas with abundance $X_{i,0}$ at a rate $A(t)$. We adopt the star formation rate by Kennicutt (1998), the IMF by Kroupa, Tout & Gilmore (1993) and a double-exponential infall law of the two-infall model. We assume that the first episode of gas accretion occurs on a time-scale of the order of 1 Gyr, whereas the second on a time-scale of 7 Gyr. The abundances of the infalling gas, $X_i(t, 0)$, in both cases are assumed to be primordial (no metals). The two infall episodes are separated by a gap in the star formation due to the assumption of a gas threshold density for star formation (see Chiappini et al. 1997; Matteucci 2012, for details). This gap creates a little bump in the model evolutionary curves of the chemical abundances, as we will see in the following. In our computations, the prescriptions for the nucleosynthesis are taken from Karakas (2010) for low- and intermediate-mass stars ($0.8 \leq M/M_\odot \leq 8$), from Doherty et al. (2014a, b) for super-asymptotic giant branch stars ($8-9 M_\odot$), from Nomoto, Kobayashi & Tominaga (2013) for CC-SNe ($M \geq 10 M_\odot$). SNe Ia are important contributors of iron and thus have a strong impact on the chemical evolution of galaxies. In our model, for the SNe Ia we use the DDT derived by Greggio (2005) in the wide double-degenerate scenario, with $\beta = -0.9$, in combination with a production efficiency of $k_{\text{Ia}} = 2.5 \times 10^{-3} M_\odot^{-1}$, fixed by the requirement of reproducing the current rate in the Milky Way estimated by Li et al. (2011). This value is larger by a factor of ~ 2.5 with respect to that derived in Greggio & Cappellaro (2019), partly because of the different IMF and law for the star formation history adopted, partly because of the different method employed to evaluate it. Greggio & Cappellaro (2019) consider the correlation between the SNe Ia rate and the colour of the parent galaxy from various SN surveys to derive the value of k_{Ia} which best reproduces the observed level of the SNe Ia rate in galaxies of intermediate colours. Therefore, their value of k_{Ia} represents an average realization probability in galaxies. The value adopted here, instead, has been obtained specifically for the Milky Way, under the

adopted prescriptions for its star formation history. The chemical yields from SNe Ia are from Iwamoto et al. (1999), and from José & Hernanz (1998) for nova systems. Concerning the nova rate, we assume that it is a fraction of the rate of formation of white dwarfs, as first computed by D’Antona & Matteucci (1991) where details can be found. These prescriptions have been validated through the comparison with a variety of observational data, such as abundance ratios versus metallicity for many chemical elements (D, He, ^7Li , C, N, O, α -elements, Fe-peak elements, and heavier, see Grisoni, Spitoni & Matteucci 2018; Grisoni et al. 2019; Romano et al. 2010; Romano & Matteucci 2003).

For the kilonovae explosions we test various possibilities, selecting among each family of model DDTs characterized by a combination of the $(\beta, A_{i, \text{min}})$ parameters, the one which provides the best fit to the Ghirlanda et al. (2016) curves, along with its particular value of k_{kn} . The yield of Eu from merging kilonovae is then set to reproduce the solar abundance of this element at the time corresponding to the formation of the Sun, namely 9 Gyr after the starting point of the model, as reported by Lodders, Palme & Gail (2009). We found that this constraint requires a yield of $5 \times 10^{-6} M_\odot$ of Eu per event. This value is in agreement with both theoretical calculations (Korobkin et al. 2012) and observations of the AT2017gfo kilonova (Tanvir et al. 2017; Troja et al. 2017), a fact that supports our determination of α_{MNS} . Although the Eu yield from merging neutron stars is uncertain the recent event GW170817 has allowed us to restrict its value to a range of $(2 - 10) \times 10^{-6} M_\odot$. We have also computed models in which CC-SNe provide a sizable contribution to Eu. In this second case, the yield per DNS merging event has been reduced to $2 \times 10^{-6} M_\odot$, while the yield from CC-SNe has been taken from the SN2050 model of Argast et al. (2004).

6.2 Results

Fig. 9 shows a selection of our models compared to the data. The latter come from two data bases, one for the halo stars compiled by Abohalima & Frebel (2018) which includes 428 objects (crosses), and another for the generally younger disc stars compiled by Battistini & Bensby (2016) with 374 objects (squares). Abundances are expressed using the square bracket notation, where $[X/Y] = 0$ represents the logarithmic ratio between elements X and Y in the Sun. The black circles show the average trend obtained by binning the data for individual stars. The low-metallicity stars are characterized by an average overabundance of [Eu/Fe] ~ 0.4 dex; starting at [Fe/H] ~ -0.8 , the abundance ratio starts decreasing towards the solar value. This trend is typical for elements whose production time-scale is shorter than the production time-scale of iron, which in turn is determined by the explosion time of SNe Ia (see e.g. Matteucci 2012). We notice the large spread of the [Eu/Fe] ratio in the low-metallicity halo star. This is likely due to the inhomogeneous pollution of the ISM in the early stages of the star formation history of the Milky Way, as investigated by, for example, Cescutti et al. (2015) and Wehmeyer, Pignatari & Thielemann (2015), an effect which is not captured by our homogeneous model.

The models plotted on Fig. 9 encompass the range of possibilities for the DDT of merging DNS envisaged in our approach: for each value of the parameter β , we show models with the two extreme values of the minimum separation of DNS systems ($A_{i, \text{min}}$), and among the models with the same $(\beta, A_{i, \text{min}})$ parameters we plot the one with the minimum distance from curve a of Ghirlanda et al. (2016). We remark that models best-fitting curve c by Ghirlanda et al. (2016) present a very similar trend on this plot. The small loop present in all the lines at [Fe/H] $\simeq -0.6$ is the result of the hiatus in

Figure 9. Abundances of Milky Way stars compared to chemical evolution models (coloured lines) computed adopting different distribution of the separations of the DNS systems. Specifically, black, blue, and cyan solid lines are obtained with $A_{i,\min}=0.1 R_{\odot}$ and $\beta = -1, -2,$ and -3 respectively. In the same sequence, violet, red, and orange dashed lines show the results for $A_{i,\min}=1 R_{\odot}$. Models in the left-hand panel have been computed adopting kilonovae as the sole source of Eu, while models in the right-hand panel adopt a contribution from CC-SNe (see the text). Observational data are from a compilation of 426 Milky Way halo stars (green crosses) taken from JINABase (Abohalima & Frebel 2018) and 374 Milky Way thin disc stars (green squares) from Battistini & Bensby (2016). Black circles represent the average values, binned in 0.5 dex wide bins.

the star formation activity mentioned in Section 6.1. Panel (a) refers to the scenario in which merging DNS are the only contributors to the Eu production in the Galaxy, while panel (b) shows the effect of adding a contribution from CC-SNe as detailed before.

When assuming that merging DNS are the only source of Eu, the data can be roughly reproduced with a very low value of $A_{i,\min}$ in combination with a steep DDT ($\beta \lesssim -2$). Larger values of $A_{i,\min}$ result in a late contribution of Eu to the ISM so that low-metallicity stars are formed out of gas with a low Eu abundance. The effect is amplified for flatter DDTs (e.g. $\beta = -1$). Actually, even for the steepest DDT, the $[\text{Eu}/\text{Fe}]$ ratio of the models is systematically smaller than the average value of the data, with a larger discrepancy in the low-metallicity regime ($[\text{Fe}/\text{H}] \lesssim -2$). In other words, the data seem to require an early source of Eu in the chemical evolution of the Galaxy. Reichert et al. (2020) find a similar indication from the analysis of the chemical pattern in Dwarf Spheroidal galaxies. Notice that in our model, the abundance $[\text{Fe}/\text{H}]=-2$ is reached very early, at ~ 25 Myr after the start of star formation. In this early stage the Fe enrichment in the ISM is due to CC-SNe, which explode on a shorter time-scale with respect to kilonovae, due to the distribution of the coalescence delays. Even for the steepest DDT ($A_{i,\min} = 0.1 R_{\odot}$ and $\beta = -3$) 30 per cent of the explosions of each stellar generation occur with a delay longer than 25 Myr.

When assuming that also CC-SNe contribute to the Eu pollution of the ISM (panel b) all models nicely reproduce the average trend of the Milky Way stars, including the DDTs with the longest time-scale for the kilonovae explosions ($A_{i,\min}=1 R_{\odot}$ and $\beta = -1$). We notice that the models exhibit a somewhat too shallow trend of the $[\text{Eu}/\text{Fe}]$ ratio as $[\text{Fe}/\text{H}]$ increases from ~ -1 to 0, with respect to the data, especially in the case of $A_{i,\min}=1$, that is, for DDTs with long pollution time-scales. The flattening of the $[\text{Eu}/\text{Fe}]$ ratio in the disc is, at least partly, the result of adopting Fe yields from CC-SNe of Nomoto et al. (2013), which include the so-called hypernovae and produce more Fe than the models by Woosley et al. (1994) adopted in Matteucci et al. (2014). Other possibilities to produce a steep $[\text{Eu}/\text{Fe}]$ trend in disc stars are discussed in Hotokezaka, Beniamini & Piran (2018), Côté et al. (2019), and Schönrich & Weinberg (2019).

7 SUMMARY AND CONCLUSIONS

The DDT of merging DNS can be constrained by considering its impact on a number of astrophysical measurements: (i) the cosmic rate of SGRBs, (ii) the chemical abundance pattern of elements synthesized in kilonova explosions, and (iii) the relation between the merging neutron stars events and the properties of the parent galaxies. This issue has been considered in various papers (e.g. Côté et al. 2019; Simonetti et al. 2019) to the general conclusion that (i) and (iii) require a sizable fraction of events at late times, while (ii) points to a large number of prompt events, if elements like Eu should be mostly produced by kilonovae. In this paper, we further test whether the three observational constraints can be met with a unique DDT by considering a variety of astrophysically motivated possibilities for the DDTs.

In order to figure out these possibilities we focus on the characteristics brought about by the clock which controls the merging event. Since the delay time is the sum of the evolutionary lifetime of the secondary component of the binary system and the coalescence lifetime of the DNS, the distribution of the total delay time is a function of the mass of the secondary component and of the total mass, separation and eccentricity of the DNS system. We have computed Monte Carlo simulations to derive the distribution of the coalescence time-scales assuming that the distributions of the separations, total masses, and eccentricity follow power laws with exponents (β, γ, ρ), respectively. Since the large majority of explosions within a Hubble time are provided by systems with separations smaller than $\sim 8 R_{\odot}$, and the total mass of the DNS system ranges between ~ 2 and $4 M_{\odot}$, the assumption of smooth distributions for these variables (in the relevant ranges) seems adequate. In the simulations, we have implemented a scheme to describe the effect of the kick due to an asymmetric explosion of the second SN. The distribution of the delays due to the evolutionary lifetimes has been derived analytically, and folding the two distributions we have obtained the distributions of the total delay times for a variety of parameters, which is meant to cover a wide range of astrophysically plausible situations.

Fig. 10 illustrates the results.

Figure 10. DDT of merging DNS systems for a selection of the parameters characterizing the distribution of the separations A_i . For each value of the β parameter (indicated with the arrows) we show the distributions obtained with three values of the minimum separation $A_{i,\min} = 0.2 R_\odot$ (blue and green), $0.5 R_\odot$ (red and magenta), and $1 R_\odot$ (black and purple). For each of the β and $A_{i,\min}$ options, we plot all combinations of the other parameters, in solid lines we highlight the $(\gamma, \rho) = (-10, 0)$ one.

(i) The DDT shows an initial peak in the range $4.5 \lesssim \tau_d/\text{Myr} \lesssim 32$ followed by power-law decline. This characteristic stems from the clock controlling the events, which is the composition of the evolutionary lifetime of the secondary star and the time taken by the gravitational waves radiation to bring the system into contact.

(ii) The power-law exponent which describes the distribution at (relatively) long delay times is close to $s = 0.25 \times \beta - 0.75$. In most of our explored cases the delay time at which this regime sets in is short (~ 0.1 Gyr), but for some specific combinations of the parameters (e.g. $\beta = -3$, $A_{i,\min} = 1 R_\odot$, and $\rho = 1$) this epoch becomes as late as a few Gyr.

(iii) The strength of the peak is very sensitive to the parameters β and $A_{i,\min}$, taken to describe the slope of the distribution of the separations and the minimum separation of the DNS systems when they form.

(iv) The parameters γ and ρ have a negligible effect on the slope of the DDT, but they affect the strength of the peak. In general, mass distributions which favour high values of M_{DN} and eccentricity distributions which favour high values of e yield more systems with short delay times. However, there is a considerable interplay between the three parameters which determine the modifications of the DDT as response to variations of β , γ , and ρ .

(v) Decreasing $A_{i,\max}$ implies a reduction of the number of mergings at very late epochs, but this effect can be appreciated when $A_{i,\max}$ becomes smaller than a few R_\odot , which seems very unlikely.

In the literature, it is often assumed that the DDT of merging neutron stars can be described as a pure power law: this is not correct, since at short delay times the DDT is characterized by a plateau (item (i) above). The width of the plateau is equal to the difference between the evolutionary lifetimes of the least massive and of the most massive neutron star progenitors. In our computations, we have

Figure 11. Fraction of systems with delay times shorter than 32 Myr for the various cases considered here. For each value of β , we plot the fractions as function of $A_{i,\min}$, reported on the x-axis. The point type encodes the values of γ and ρ as labelled. For each β , the dotted line connects the fractions F_p for the case $(\gamma = -10$ and $\rho = 1)$ for illustration. Green crosses show the prompt fractions for $A_{i,\min} = 0.5 R_\odot$, in the case of correlation between M_{DN} and A_i . See the text for details.

adopted a mass range of $9 \leq M/M_\odot \leq 50$, which corresponds to a width of ~ 27 Myr.

Another common assumption concerns the slope of the power law decline, taken to be $s = -1$. This is also not correct, since this slope is a function of the shape of the distribution of the separations of the DNS systems at birth [item (ii) above]. The power-law regime, which follows the plateau, sets in at a delay time which depends on the minimum separation of the DNS systems at birth. In Appendix A, these properties are justified analytically.

We notice that the DDT for merging DNS in Eldridge et al. (2019) BPS models show similar characteristics, namely an early peak of ~ 30 Myr duration, followed by a power-law decline with slope -1 . While the results of BPS codes can be ascribed to the combination of the prescriptions adopted in the calculation, in our derivation these characteristics are directly related to basic astrophysical properties, that is, the mass of neutron stars progenitors, and the distribution of the separations of the DNS systems at birth. This makes it possible to obtain an easy, yet effective, parametrization of DDT.

Fig. 11 shows the fraction (F_p) of systems which merge within 32 Myr for the variety of combination of the parameters considered, all of which appear to have some impact on this fraction. As the distribution of A_i becomes steeper F_p increases, and, for a given β , the lower the limit on A_i the larger the fraction of *prompt* events. These two parameters appear equally important, with, for example, the same value of F_p obtained with the combinations $(\beta = -1$ and $A_{i,\min} = 0.2 R_\odot)$ and $(\beta = -2$ and $A_{i,\min} = 0.5 R_\odot)$. The fraction of *prompt* events also depends on the distributions of the total mass and of the eccentricity of the DNS systems, although to a lesser extent, especially when the distribution of A_i has a large abundance of binaries with low separations. We notice that the distributions discussed so far do not consider the possibility of a correlation between the separation A_i and the mass of the DNS system which may result from a more effective shrinkage of the more massive systems

during the CE phase, similar to the *CLOSE DD* variety of Greggio (2005) models for SNe Ia. If this were the case, for a given β , the distribution of the GWR delays would be steeper, and the fraction of prompt events would be higher. We tested this possibility computing the DDT for the cases $A_{i, \min} = 0.5 R_{\odot}$, $\beta = -1, -3$, and $\rho = -0.5, 0, 1$, and assuming the (arbitrary) relation $M_{\text{DN}} - 2 = 1.4/\sqrt{A_i}$. The results are shown on Fig. 11 as green crosses. It appears that the effect of adopting a correlation between M_{DN} and A_i is modest, and on the same order of that due to a variation of the distribution of the eccentricities at fixed β and $A_{i, \min}$.

It turns out that the currently available data on the cosmic rate of SGRBs do not lead to a strong constraint on the parameters controlling the DDT, with the various models yielding an acceptable representation of the data, within the observational uncertainty. A mild preference for models with a sizable component at relatively long delay times (e.g. $\beta = -1$) is present. More stringent indications can be achieved with a larger data base of SGRBs (and kilonova) events. The measurement of the SGRB rates in galaxies with different star formation history, and the correlation with the properties of the parent galaxies, can greatly help in assessing the shape of the DDT, as currently done for SNe Ia (e.g. Botticella et al. 2017). The association with early type galaxies of some SGRBs, and of the GW170817 event, support a shallow slope for the DDT of merging DNS. However, due to the steep slope of the DDT (e.g. dropping by factor of $10^{3.8}$ from 20 Myr to 10 Gyr), a modest recent star formation activity could give rise to a merging DNS even in a generally old galaxy. More precise constraints will come from future observational campaigns aimed at measuring the rate of these events in galaxies of different type.

Notwithstanding the loose constraints on the DDT from the redshift distribution of SGRBs, their local rate, as well as the local rate of kilonovae, allows us to derive a robust indication of the fraction of neutron star progenitors which should follow the evolutionary path leading to DNS systems merging within a Hubble time. This fraction turns out to be $\alpha_{\text{MNS}} \sim 1$ per cent. A number of uncertainties bear upon the determination of α_{MNS} , including those related to the local rate of kilonovae, the approximations introduced in our procedure to evaluate k_{kn} , and the possible systematic with age and metallicity of the kilonova production from stellar populations. Nevertheless, had we found a much different value for k_{kn} , and in turn α_{MNS} , it would be hard to account for the solar Eu abundance with the standard chemical evolution model. We point out that in the chemical evolution model we follow not only the [Eu/Fe] versus [Fe/H], but also the abundances of the elements produced by massive stars in the same mass range of merging neutron stars. Therefore, also the Fe and α -element abundances are affected by the adopted value of α_{MNS} . Our chemical evolution model follows 40 species and it is aimed at reproducing the [X/Fe] versus [Fe/H] relations together with the solar abundances of all the considered elements.

With the same approach adopted here Greggio & Cappellaro (2019) find that in order to account for the observed rate of SNe Ia in SN surveys, ~ 3 per cent of the stars with mass between 2.5 and 9 M_{\odot} should be found in systems which evolve to the final explosion. Although the details of the evolution of the two kinds of explosive events are different, still the observed rates indicate that a few per cent of the progenitors should be found in close binaries of the variety which secures the final explosion in a Hubble time. This is a strong constraint to the BPS models and may be used to appraise the input ingredients, for example those which impact on the fraction of systems which are disrupted in the course of the evolution.

With our measurement of α_{MNS} we have computed models for the trend of [Eu/Fe] versus [Fe/H] in the chemical evolution of the Milky

Way. If merging DNS are the only contributors to the Eu abundance in the ISM, a very prompt release of this element is necessary to reproduce the high [Eu/Fe] ratio in low-metallicity, halo stars. However even with the DDT which in our models has the highest *prompt* fraction we cannot match the observed level of the abundance ratio. Resorting to a steeper distribution of the separations (lower β) or to an even smaller minimum separation ($A_{i, \min}$) does not solve the problem because the curves become insensitive to these parameters. One possible solution consists in assuming some Eu production from CC-SNe which would release Eu to the ISM at the same pace as their iron production. In our models, the data are well matched with a comparable contribution to Eu from CC-SNe and kilonovae. While the discrepancy on the [Eu/Fe] ratio is more critical for the low-metallicity stars, the assumption of a contribution to Eu from CC-SNe leads to a better match over the whole Fe range. Unfortunately, in this case, the Eu production from CC-SNe obscures the contribution from kilonovae, so that it is very difficult to discriminate between the various DDTs.

To conclude, based on a thorough exploration of the possibilities for the DDT of merging DNS, the current data on the redshift distribution of SGRBs and on the trend of the Eu to Fe ratio in Milky Way stars leads to the following conclusions:

- (i) approximately 1 per cent of the neutron star progenitors should be found in binary systems which evolve up to the final exploding event;
- (ii) an additional source of Eu is required to account for the high [Eu/Fe] ratio in the Galactic halo stars, besides the kilonova events. This applies to a lesser extent also to disc stars, so that a contribution from ordinary CC-SNe is favoured;
- (iii) no strong constraint on the DDT can currently be derived from the observations, so that it is possible to match all the currently available data with the same DDT.

APPENDIX: ANALYTICAL DERIVATION OF THE DISTRIBUTION OF THE COALESCENCE TIMES

The time taken by the gravitational waves radiation to bring into contact the two neutron stars members of a binary with total mass, initial separation, and eccentricity (M_{DN}, A, e) can be approximated as

Figure A1. Limits on eccentricity imposed by the limits on the separations.

Figure A2. Correction factor to the straight power law as a function of τ_{GW} for various options of the parameters β and ρ , as labelled. Solid lines are computed with $M_{\text{DN}}=2.2 M_{\odot}$, and dashed lines with $M_{\text{DN}}=4 M_{\odot}$. Blue, green, and red lines show the correction factor respectively for $A_{i,\text{min}}=0.1, 0.5, \text{ and } 1 R_{\odot}$ and $A_{i,\text{max}}=50 R_{\odot}$. Black dotted lines illustrate how the correction factor is modified when $A_{i,\text{max}}=30 R_{\odot}$ is adopted.

in equation (3). In Simonetti et al. (2019), we derived the distribution of τ_{GW} for systems with $e = 0$; here we take into account the dependence on the eccentricity, but consider the case of constant $M_{\text{DN}} = M_{\text{DN}0}$.

The contribution to the number of systems with delay τ_{GW} from systems with total mass $M_{\text{DN}0}$, separation A and eccentricity e is :

$$dn(\tau_{\text{GW}}, e) = n(e) \times n(A^*) de dA^*, \quad (\text{A1})$$

where $n(e)$, $n(A)$ are the distribution functions of the eccentricity and of the separations, the latter evaluated at

$$A^* = \left(\frac{M_{\text{DN}0}^3 \tau_{\text{GW}}}{0.6(1-e^2)^{3.5}} \right)^{0.25} R_{\odot}. \quad (\text{A2})$$

with $M_{\text{DN}0}$ in solar masses and τ_{GW} in Gyr. Integrating on the eccentricities, we get

$$n(\tau_{\text{GW}})d\tau_{\text{GW}} = d\tau_{\text{GW}} \int_0^1 n(e) \times n(A^*) \left| \frac{\partial A}{\partial \tau_{\text{GW}}} \right| de. \quad (\text{A3})$$

Substituting

$$\frac{\partial A}{\partial \tau_{\text{GW}}} \propto \tau_{\text{GW}}^{-0.75} \times (1-e^2)^{-7/8} \quad (\text{A4})$$

equation (A3) becomes

$$n(\tau_{\text{GW}}) \propto \tau_{\text{GW}}^{-0.75} \int_0^1 n(e) \times n(A^*) \times (1-e^2)^{-7/8} de. \quad (\text{A5})$$

Adopting $n(e) \propto e^{\rho}$ and

$$n(A) \propto \begin{cases} 0 & \text{in } A < A_{i,\text{min}} \\ A^{\beta} & \text{in } A_{i,\text{min}} \leq A \leq A_{i,\text{max}} \\ 0 & \text{in } A > A_{i,\text{max}} \end{cases} \quad (\text{A6})$$

we get

$$n(\tau_{\text{GW}}) \propto \tau_{\text{GW}}^{-0.75+0.25\beta} \int_{e_{\text{min}}}^{e_{\text{max}}} \frac{e^{\rho}}{(1-e^2)^{7(1+\beta)/8}} de \quad (\text{A7})$$

where e_{min} and e_{max} are, respectively, the minimum and maximum values of the eccentricity which correspond to $A_{i,\text{min}}$ and $A_{i,\text{max}}$. Equation (A7) shows that the distribution of the GWR delays scales proportionally to a power law with exponent $s = -0.75 + 0.25\beta$ modified by a factor, $\text{CF}(\tau_{\text{GW}})$, which accounts for the limits on the parameter space due to the conditions on the allowed range of separations. On Fig. 2, one can see that at a given τ_{GW} a lower limit on A implies lower limit on e greater than 0, and an upper limit on A implies an upper limit on e smaller than 1. In fact:

$$\begin{cases} e_{\text{min}}^2 = \max \left[0; 1 - \left(\frac{\tau_{\text{GW}} M_{\text{DN}0}^3}{0.6 A_{i,\text{min}}^4} \right)^{2/7} \right] \\ e_{\text{max}}^2 = \min \left[1; 1 - \left(\frac{\tau_{\text{GW}} M_{\text{DN}0}^3}{0.6 A_{i,\text{max}}^4} \right)^{2/7} \right]. \end{cases}$$

These limits are shown on Fig. A1 as function of τ_{GW} for our adopted minimum and maximum values of M_{DN} , and various options for the range of separations. If $A_{i,\text{max}}$ is sufficiently large, the upper limit e_{max} is close to 1 for all GWR delays within a Hubble time, irrespectively of M_{DN} . The effect of the lower limit $A_{i,\text{min}}$ is much more important: it implies a shrinkage of the range of eccentricities providing

short GWR delays by an amount which depends on both $A_{i, \min}$ and M_{DN} .

Fig. A2 shows the correction factor $\text{CF}(\tau_{\text{GW}})$ normalized to its maximum value, for a few combinations of the parameters.

(i) The correction factor is very small at short τ_{GW} ; it increases with increasing τ_{GW} up to a maximum reached at τ_{GW}^* , beyond which it remains constant.

(ii) The value of τ_{GW}^* increases with $A_{i, \min}$ increasing, and, for $A_{i, \min} = 1 R_{\odot}$, it is of (9.5, 57) Myr, respectively for $M_{\text{DN}} = 4$ and 2, $2 M_{\odot}$.

(iii) The correction factor depends on $A_{i, \max}$ only if the distribution of the separation is relatively flat, and even in that case it appears quite mild.

(iv) Steeper values of β and flatter values of ρ lead to a sharper variation of $\text{CF}(\tau_{\text{GW}})$ approaching τ_{GW}^* .

Equation (A7) and the correction factor shown on Fig. A2 have been derived under the assumption that the variables (A , e) are independent. When a correlation is introduced between A_j/A_i and eccentricity, as in the cases shown on Figs 4 and 5, some modifications on the correction factor set in, especially in the vicinity of τ_{GW}^* .
